Managing Smile Risk

Patrick S. Hagan¹, Deep Kumar†, Andrew S. Lesniewski‡, and Diana E. Woodward§

Abstract
Market smiles and skews are usually managed by using local volatility models à la Dupire. We discover that the dynamics of the market smile predicted by local vol models is opposite of observed market behavior: when the price of the underlying decreases, local vol models predict that the smile shifts to higher prices; when the price increases, these models predict that the smile shifts to lower prices. Due to this contradiction between model and market, delta and vega hedges derived from the model can be unstable and may perform worse than naive Black-Scholes’ hedges.

To eliminate this problem, we derive the SABR model, a stochastic volatility model in which the forward value satisfies
\[ d\hat{F} = \hat{a}\hat{F}^{\beta}dW_1 \]
\[ d\hat{a} = \nu \hat{a} dW_2 \]
and the forward \(\hat{F}\) and volatility \(\hat{a}\) are correlated: \(dW_1 dW_2 = \rho dt\). We use singular perturbation techniques to obtain the prices of European options under the SABR model, and from these prices we obtain explicit, closed-form algebraic formulas for the implied volatility as functions of today’s forward price \(f(0)\) and the strike \(K\). These formulas immediately yield the market price, the market risks, including wessa and volga risks, and show that the SABR model captures the correct dynamics of the smile. We apply the SABR model to USD interest rate options, and find good agreement between the theoretical and observed smiles.

Key words. smiles, skew, dynamic hedging, stochastic vols, volga, vanna

1 Introduction
European options are often priced and hedged using Black’s model, or, equivalently, the Black-Scholes model. In Black’s model there is a one-to-one relation between the price of a European option and the volatility parameter \(\sigma_B\). Consequently, option prices are often quoted by stating the implied volatility \(\sigma_B\), the unique value of the volatility which yields the option’s dollar price when used in Black’s model. In theory, the volatility \(\sigma_B\) in Black’s model is a constant. In practice, options with different strikes \(K\) require different volatilities \(\sigma_B\) to match their market prices. See figure 1. Handling these market skews and smiles correctly is critical to fixed income and foreign exchange desks, since these desks usually have large exposures across a wide range of strikes. Yet the inherent contradiction of using different volatilities for different options makes it difficult to successfully manage these risks using Black’s model.
The development of local volatility models by Dupire [2], [3] and Derman-Kani [4], [5] was a major advance in handling smiles and skews. Local volatility models are self-consistent, arbitrage-free, and can be calibrated to precisely match observed market smiles and skews. Currently these models are the most popular way of managing smile and skew risk. However, as we shall discover in section 2, the dynamic behavior of smiles and skews predicted by local vol models is exactly opposite the behavior observed in the marketplace: when the price of the underlying asset decreases, local vol models predict that the smile shifts to higher prices; when the price increases, these models predict that the smile shifts to lower prices. In reality, asset prices and market smiles move in the same direction. This contradiction between the model and the marketplace tends to destabilize the delta and vega hedges derived from local volatility models, and often these hedges perform worse than the naive Black-Scholes’ hedges.

To resolve this problem, we derive the SABR model, a stochastic volatility model in which the asset price and volatility are correlated. Singular perturbation techniques are used to obtain the prices of European options under the SABR model, and from these prices we obtain a closed-form algebraic formula for the implied volatility as a function of today’s forward price \( f \) and the strike \( K \). This closed-form formula for the implied volatility allows the market price and the market risks, including vanna and volga risks, to be obtained immediately from Black’s formula. It also provides good, and sometimes spectacular, fits to the implied volatility curves observed in the marketplace. See Figure 1.1. More importantly, the formula shows that the SABR model captures the correct dynamics of the smile, and thus yields stable hedges.

### 2 Reprise

Consider a European call option on an asset \( A \) with exercise date \( t_x \), settlement date \( t_s \), and strike \( K \). If the holder exercises the option on \( t_s \), then on the settlement date \( t_s \), he receives the underlying asset \( A \) and pays the strike \( K \). To derive the value of the option, define \( \hat{A}(t) \) to be the forward price of the asset for a forward contract that matures on the settlement date \( t_s \), and define \( f = \hat{A}(0) \) to be today’s forward price. Also let \( \delta(t) \) be the discount factor for date \( t \), that is, let \( \delta(t) \) be the value today of \( 1 \) to be delivered on date \( t \). Martingale pricing theory [6-9] asserts that under the “usual conditions,” there is a measure, known as the forward measure, under which the value of a European option can be written as the expected value of the payoff. The value of a call option is

\[
V_{\text{call}} = D(t_x) \left[ \hat{A}(t_x) \right] (K) - K^\uparrow (\delta(t_x)), \tag{2.1a}
\]

and the value of the corresponding European put is

\[
V_{\text{put}} = D(t_x) \left[ K - \hat{A}(t_x) \right] (\delta(t_x)) \equiv V_{\text{call}} + D(t_x)\left[ K - f \right]. \tag{2.1b}
\]

The implied volatility of the corresponding European put is

\[
V_{\text{put}} = \text{Black's formula for the implied volatility allows the market price and the market smiles to match observed market smiles.}
\]

Fig. 1.1 Implied volatility for the June 99 Eurodollar options. Shown are close-of-day values along with the volatilities predicted by the SABR model. Data taken from Bloomberg information services on March 23, 1999

Here the expectation \( \hat{F}(\cdot) \) is over the forward measure, and \( \delta(t) \) can be interpreted as “given all information available at \( t = 0 \)” Martingale pricing theory [6-9] also shows that the forward price \( \hat{F}(t) \) is a Martingale under this measure, so the Martingale representation theorem shows that \( \hat{F}(t) \) obeys

\[
d\hat{F} = C(t, *) \, dW, \quad \hat{F}(0) = f. \tag{2.1c}
\]

for some coefficient \( C(t, *) \), where \( dW \) is Brownian motion in this measure. The coefficient \( C(t, *) \) may be deterministic or random, and may depend on any information that can be resolved by time \( t \). This is as far as the fundamental theory of arbitrage free pricing goes. In particular, one cannot determine the coefficient \( C(t, *) \) on purely theoretical grounds. Instead one must postulate a mathematical model for \( C(t, *) \).

European swaptions fit within an identical framework. Consider a European swaption with exercise date \( t_e \) and fixed rate (strike) \( R_0 \). Let \( \hat{R}_1(t) \) be the swaption’s forward swap rate as seen at date \( t \), and let \( R_1 = \hat{R}_1(0) \) be the forward swap rate as seen today. In [9] Jamshidean shows that one can choose a measure in which the value of a payer swaption is

\[
V_{\text{pay}} = L_0 \mathbb{E} \left[ \left( \hat{R}_1(t_e) - R_0 \right)^+ \right] | \mathcal{F}_t, \tag{2.2a}
\]

and the value of a receiver swaption is

\[
V_{\text{rec}} = L_0 \mathbb{E} \left[ R_0 - \hat{R}_1(t_e)^+ \right] | \mathcal{F}_t \equiv V_{\text{pay}} + L_0 \left[ R_0 - R_1 \right]. \tag{2.2b}
\]

Here the level \( L_0 \) is today’s value of the annuity, which is a known quantity; and \( \hat{F} \) is the expectation over the level measure of Jamshidean [9]. In Appendix A it is also shown that the PV01 of the forward swap; like the
discount factor rate $\hat{\delta}(t)$ is a Martingale in this measure, so once again

$$d\hat{\delta}(t) = C(t, \ast) \, d\tilde{W}(t), \quad \hat{\delta}(0) = \delta_0,$$

(2.2c)

where $d\tilde{W}$ is Brownian motion. As before, the coefficient $C(t, \ast)$ may be deterministic or random, and cannot be determined from fundamental theory. Apart from notation, this is identical to the framework provided by equations (2.1a–2.1c) for European calls and puts. Caplets and floorlets can also be included in this picture, since they are just one period payer and receiver swaptions. For the remainder of the paper, we adopt the notation of (2.1a–2.1c) for general European options.

# 2.1 Black’s model and implied volatilities

To go any further requires postulating a model for the coefficient $C(t, \ast)$. In [10], Black postulated that the coefficient $C(t, \ast)$ is $\sigma_{\ast}^2(t)$, where the volatility $\sigma_{\ast}$ is a constant. The forward price $\hat{F}(t)$ is then geometric Brownian motion:

$$d\hat{F}(t) = \sigma_{\ast}^2(t) \, d\tilde{W}(t), \quad \hat{F}(0) = f.$$  \hfill (2.3)

Evaluating the expected values in (2.1a, 2.1b) under this model then yields Black’s formula,

$$V_{\text{call}} = D(t, t_s) \, \Phi(d_1(t)) - K \, e^{-r t_s} \, \Phi(d_2(t)), \quad (2.4a)$$

$$V_{\text{put}} = V_{\text{call}} + D(t, t_s) \, (K-f), \quad (2.4b)$$

where

$$d_{1,2} = \frac{\log(F_{\ast} / K) \pm \sqrt{\log\left(\frac{F_{\ast}}{K}\right) - \frac{(r - \delta_0) \, t_s}{2} }}{\sigma_{\ast} \, \sqrt{t_s}}$$  \hfill (2.4c)

for the price of European calls and puts, as is well known [10], [11], [12].

All parameters in Black’s formula are easily observed, except for the volatility $\sigma_{\ast}$. An option’s implied volatility is the value of $\sigma_{\ast}$ that needs to be used in Black’s formula so that this formula matches the market price of the option. Since the call (and put) prices in (2.4a – 2.4c) are increasing functions of $\sigma_{\ast}$, the volatility $\sigma_{\ast}$ implied by the market price of an option is unique. Indeed, in many markets it is standard practice to quote prices of payer and receiver swaptions. For the remainder of the paper, we adopt the notation of (2.1a–2.1c) for general European options.

For example, suppose that our 1 month option book is long high strike and short low strike options with a total

$$\Delta = \Delta_1$$

for 1 month, 3 month, 6 month, and 12 month European options on an asset with forward price $F_{\ast}$.

The derivation of Black’s formula presumes that the volatility $\sigma_{\ast}$ is a constant for each underlying asset $A$. However, the implied volatility needed to match market prices nearly always varies with both the strike $K$ and the time-to-exercise $t_s$. See Figure 2.1. Changing the volatility $\sigma_{\ast}$ means that a different model is being used for the underlying asset for each $K$ and $t_s$. This causes several problems managing large books of options.

The first problem is pricing exotic options. Suppose one needs to price a call option with strike $K_1$ which has, say, a down-and-out knock-out at $K_2 < K_1$. Should we use the implied volatility at the call’s strike $K_1$, the implied volatility at the barrier $K_2$, or some combination of the two to price this option? Clearly, this option cannot be priced without a single, self-consistent, model that works for all strikes without “adjustments.”

The second problem is hedging. Since different models are being used for different strikes, it is not clear that the delta and vega risks calculated at one strike are consistent with the same risks calculated at other strikes. For example, suppose that our 1 month option book is long high strike options with a total $\Delta = \Delta_1$ and low long strike options with a total $\Delta = -\Delta_1$. Is our is our option book really $\Delta$-neutral, or do we have residual delta risk that needs to be hedged? Since different models are used at each strike, it is not clear that the risks offset each other. Consolating vega risk raises similar concerns. Should we assume parallel or proportional shifts in volatility to calculate the total vega risk of our book? More explicitly, suppose that $\sigma_{\ast}$ is 20% at $K = 100$ and 24% at $K = 90$, as shown for the 1m options in Figure 2.1 Should we calculate vega by bumping $\sigma_{\ast}$ by, say, 0.2% for both options? Or by bumping $\sigma_{\ast}$ by 0.2% for the first option and by 0.24% for the second option? These questions are critical to effective book management, since this requires consolidating the delta and vega risks of all options on a given asset before hedging, so that only the net exposure of the book is hedged. Clearly one cannot answer these questions without a model that works for all strikes $K$.

The third problem concerns evolution of the implied volatility curve $\sigma_{\ast}(K)$. Since the implied volatility $\sigma_{\ast}$ depends on the strike $K$, it is likely to also depend on the current value $f$ of the forward price: $\sigma_{\ast} = \sigma_{\ast}(f, K)$. In this case there would be systematic changes in $\sigma_{\ast}$ as the forward price $f$ of the underlying changes See Figure 2.1. Some of the vega risks of Black’s model would actually be due to changes in the price of the underlying asset, and should be hedged more properly (and cheaply) as delta risks.

---

2.2 Local volatility models. An apparent solution to these problems is provided by the local volatility model of Dupire [2], which is also attributed to Derman [4, 5]. In an insightful work, Dupire essentially argued that Black was to bold in setting the coefficient $c(t, x)$ to $a_\sigma F$. Instead one should only assume that $c(t, x) = a_\sigma(x, t)$, the unknown local volatility function, in the forward measure. Dupire argued that instead of theorizing about the unknown local volatility function $a_\sigma(x, t)$, one should only assume that $a_\sigma(x, t)$ is a function of $F$ and $t$ directly from the marketplace by “calibrating” the local volatility model to market prices of liquid European options.

In calibration, one starts with a given local volatility function $a_\sigma(t, F)$, and evaluates

$$V_{\text{call}}(t_0, K) = D(t_0) \left[ \hat{F}(t_0) - K \right] \left[ \hat{F}(0) = f_0 \right]$$

(2.5a)

in the forward measure. Dupire argued that instead of theorizing about the unknown local volatility function $a_\sigma(t, F)$, one should obtain $a_\sigma(t, F)$ directly from the marketplace by “calibrating” the local volatility model to market prices of liquid European options.

In calibration, one starts with a given local volatility function $a_\sigma(t, F)$, and evaluates

$$V_{\text{call}}(t_0, K) = D(t_0) \left[ \hat{F}(t_0) - K \right] \left[ \hat{F}(0) = f_0 \right]$$

(2.5b)

$$= V_{\text{call}} + D(t_0) (F - K)$$

(2.5c)

to obtain the theoretical prices of the options; one then varies the local volatility function $a_\sigma(t, F)$ until these theoretical prices match the actual market prices of the option for each strike $K$ and exercise date $t_0$. In practice liquid markets usually exist only for options with specific exercise dates $t_0^0, t_0^1, t_0^2, \ldots$; for example, for 1m, 2m, 3m, 6m, and 12m from today. Commonly the local vols $a_\sigma(t_0, F)$ are taken to be piecewise constant in time:

$$a_\sigma(t_0, F) = a_\sigma^j(F)$$

for $t < t_0^j$.

$$a_\sigma(t_0, F) = a_\sigma^j(F)$$

for $t_0^j < t < t_0^{j+1}$, $j = 2, 3, \ldots$ (2.6)

$$a_\sigma(t_0, F) = a_\sigma^j(F)$$

for $t > t_0^{j+1}$.

One first calibrates $a_\sigma^j(F)$ to reproduce the option prices at $t_0^j$ for all strikes $K$; then calibrates $a_\sigma^{j+1}(F)$ to reproduce the option prices at $t_0^{j+1}$, for all $K$, and so forth. This calibration process can be greatly simplified by using the results in [13] and [14]. There we solve to obtain the prices of European options under the local volatility model (2.5a–2.5c), and from these prices we obtain explicit algebraic formulas for the implied volatility of the local volatility model.

Once $a_\sigma(t_0, F)$ has been obtained by calibration, the local volatility model is a single, self-consistent model which correctly reproduces the market prices of calls (and puts) for all strikes $K$ and exercise dates $t_0$ without “adjustment.” Prices of exotic options can now be calculated from this model without ambiguity. This model yields consistent delta and vega risks for all options, so these risks can be consolidated across strikes. Finally, perturbing $f$ and re-calculating the option price enables one to determine how the implied volatilities change with changes in the underlying asset price. Thus, the local volatility model thus provides a method of pricing and hedging options in the presence of market smiles and skew.

In [13] and [14] singular perturbation methods were used to analyze this model. There it was found that European call and put prices are given by Black’s formula (2.4a–2.4c) with the implied volatility

$$a_\sigma(K, f) = a_\sigma \left( \frac{1}{2} (F + K) \right) \left( 1 + \frac{1}{24} a_\sigma^2 \left( \frac{1}{2} (K + F) \right) f^2 + \cdots \right)$$

(2.8)

On the right hand side, the first term dominates the solution and the second term provides a much smaller correction. The omitted terms are very small, usually less than 1% of the first term.

The behavior of local volatility models can be largely understood by examining the first term in (2.8). The implied volatility depends on both the strike $K$ and the current forward price $f$. So suppose that today the forward price is $f_0$ and the implied volatility curve seen in the marketplace is $a_\sigma^j(K)$. Calibrating the model to the market clearly requires choosing the local volatility to be

$$a_\sigma^j(F) = a_\sigma^j(2F - f_0, 1 + \cdots)$$

(2.9)

Now that the model is calibrated, let us examine its predictions. Suppose that the forward value changes from $f_0$ to some new value $f$. From (2.8), (2.9) we see that the model predicts that the new implied volatility curve is

$$a_\sigma(K, f) = a_\sigma^j(2F - f_0, 1 + \cdots)$$

(2.10)

for an option with strike $K$, given that the current value of the forward price is $f$. In particular, if the forward price $f_0$ increases to $f$, the implied volatility curve moves to the left; if $f_0$ decreases to $f$, the implied volatility curve moves to the right. Local volatility models predict that the market smile/skew moves in the opposite direction as the price of the underlying asset. This is opposite to typical market behavior, in which smiles and skews move in the same direction as the underlying.
To demonstrate the problem concretely, suppose that today’s implied volatility is a perfect smile

\[ \sigma_t^2(K) = \alpha + \beta (K - f_0)^2 \tag{2.11a} \]

around today’s forward price \( f_0 \). Then equation (2.8) implies that the local volatility is

\[ \sigma_{loc}(T) = \alpha + 3\beta (f - f_0) + \cdots. \tag{2.11b} \]

As the forward price \( f \) evolves away from \( f_0 \) due to normal market fluctuations, equation (2.8) predicts that the implied volatility is

\[ \sigma_t(K, f) = \alpha + \beta [K - (\frac{f_0}{2} - f / 2)]^2 + \frac{3}{2} \beta (f - f_0)^2 + \cdots, \tag{2.11c} \]

The implied volatility curve not only moves in the opposite direction as the underlying, but the curve also shifts upward regardless of whether \( f \) increases or decreases. Exact results are illustrated in Figures 2.2 – 2.4. There we assumed that the local volatility \( \sigma_{loc}(f) \) was given by (2.11b), and used finite difference methods to obtain essentially exact values for the option prices, and thus implied volatilities.

Hedges calculated from the local volatility model are wrong. To see this, let \( BS(f, K, \sigma_t, t_0) \) be Black’s formula (2.4a–2.4c) for, say, a call option. Under the local volatility model, the value of a call option is given by Black’s formula

\[ V_{call} = BS(f, K, \sigma_{loc}(f), t_0) \tag{2.12a} \]

with the volatility \( \sigma_{loc}(f) \) given by (2.8). Differentiating with respect to \( f \) yields the \( \Delta \) risk

\[ \Delta = \frac{V_{call}}{df} = \frac{3\beta}{df} + \frac{dBS}{d\sigma} \frac{d\sigma_{loc}(f)}{df}. \tag{2.12b} \]

The original Black model yields more accurate hedges than the local volatility model, even though the local vol model is self-consistent across strikes and Black’s model is inconsistent. Local volatility models are also peculiar theoretically. Using any function for the local volatility \( \sigma_{loc}(f, \hat{f}) \) except for a power law,

\[ \sigma_t(t, \hat{f}) = \alpha(t) \hat{f}^\beta, \tag{2.13} \]

predicted by the local volatility model. The first term is clearly the \( \Delta \) risk one would calculate from Black’s model using the implied volatility from the market. The second term is the local volatility model’s correction to the \( \Delta \) risk, which consists of the Black vega risk multiplied by the predicted change in \( \sigma_t \) due to changes in the underlying forward price \( f \). In real markets the implied volatility moves in the opposite direction as the direction predicted by the model. Therefore, the correction term needed for real markets should have the opposite sign as the correction predicted by the local volatility model. The original Black model yields more accurate hedges than the local volatility model, even though the local vol model is self-consistent across strikes and Black’s model is inconsistent.

Local volatility models are also peculiar theoretically. Using any function for the local volatility \( \sigma_{loc}(t, \hat{f}) \) except for a power law,

\[ \sigma_t(t, \hat{f}) = \alpha(t) \hat{f}^\beta, \tag{2.14} \]
introduces an intrinsic “length scale” for the forward price \( \hat{F} \) into the model. That is, the model becomes inhomogeneous in the forward price \( \hat{F} \). Although intrinsic length scales are theoretically possible, it is difficult to understand the financial origin and meaning of these scales [15], and one naturally wonders whether such scales should be introduced into a model without specific theoretical justification.

2.3 The SABR model. The failure of the local volatility model means that we cannot use a Markovian model based on a single Brownian motion to manage our smile risk. Instead of making the model non-Markovian, or basing it on non-Brownian motion, we choose to develop a two-factor model. To select the second factor, we note that most markets experience both relatively quiescent and relatively chaotic periods. This suggests that volatility is not constant, but is itself a function of time. Respecting the preceding discussion, we choose the unknown coefficient \( C(t, \sigma) \) to be \( \hat{\alpha} \beta \), where the “volatility” \( \hat{\alpha} \) is itself a stochastic process. Choosing the simplest reasonable process for \( \hat{\alpha} \) now yields the “stochastic volatility” model, which has become known as the SABR model. In this model, the forward price and volatility are

\[
\begin{align*}
\hat{d}F &= \hat{\alpha} \hat{F} dW_1, \quad \hat{F}(0) = \hat{f} \\
\hat{d}\hat{\alpha} &= \hat{v} \hat{\alpha} dW_1, \quad \hat{\alpha}(0) = \hat{\alpha}_0
\end{align*}
\]

(2.15a)

under the forward measure, where the two processes are correlated by

\[
\hat{d}W_1 \, dW_1 = \rho dt.
\]

(2.15c)

Many other stochastic volatility models have been proposed, for example [16], [17], [18], [19]. However, the SABR model has the virtue of being the simplest stochastic volatility model which is homogeneous in \( \hat{F} \) and \( \hat{\alpha} \). We shall see that the SABR model can be used to accurately fit the implied volatility curves observed in the marketplace for any single exercise date \( \hat{t} \). More importantly, it predicts the correct dynamics of the implied volatility curves. This makes the SABR model an effective means to manage the smile risk in markets where each asset only has a single exercise date; these markets include the swaption and caplet/floorlet markets.

As written, the SABR model may or may not fit the observed volatility surface of an asset which has European options at several different exercise dates; such markets include foreign exchange options and most equity options. Fitting volatility surfaces requires the dynamic SABR model which is discussed in an Appendix.

It has been claimed by many authors that stochastic volatility models are models of incomplete markets, because the stochastic volatility risk cannot be hedged. This is not true. It is true that the risk to changes in \( \hat{\alpha} \) (the vega risk) cannot be hedged by buying or selling the underlying asset. However, vega risk can be hedged by buying or selling options on the asset in exactly the same way that \( \Delta \) hedging is used to neutralize the risks to changes in the price \( \hat{F} \). In practice, vega risks are hedged by buying and selling options as a matter of routine, so whether the market would be complete if these risks were not hedged is a moot question.

The SABR model (2.15a–2.15c) is analyzed in Appendix B. There singular perturbation techniques are used to obtain the prices of European options. From these prices, the options’ implied volatility \( \sigma_{I}(K, \hat{f}) \) is then obtained. The upshot of this analysis is that under the SABR model, the price of European options is given by Black’s formula,

\[
\begin{align*}
V_{\text{call}} &= D(t_0) [f/N(d_1) - KN(d_2)], \\
V_{\text{put}} &= V_{\text{call}} + D(t_0) [K - f],
\end{align*}
\]

(2.16a)

with

\[
\hat{d}_1 = \frac{\log f + \frac{1}{2} \sigma^2 \hat{t}}{\hat{\sigma} \sqrt{\hat{t}}}, \quad \hat{d}_2 = \hat{d}_1 - \sigma \sqrt{\hat{t}}.
\]

(2.16c)

where the implied volatility \( \hat{\sigma}(K, \hat{f}) \) is given by

\[
\hat{\sigma}(K, \hat{f}) = \frac{\hat{\sigma}}{\hat{A}} [1 + \frac{\hat{\sigma}^2}{2} \log^2 f/K + \frac{\hat{\sigma}^4}{24} (\log f/K + \cdots) \left( \frac{z}{\hat{\sigma}^2} \right)^{\hat{\beta}}]^{\hat{\alpha}} f^{-\hat{\beta} \hat{\nu}} K^{-\hat{\alpha} - \hat{\beta} \hat{\nu}}
\]

(2.17a)

Here

\[
\hat{z} = \frac{\hat{\alpha}}{\hat{\sigma}} (f/K)^{1 - \hat{\beta}/1.12} \log f/K
\]

(2.17b)

and \( \hat{A}(\hat{z}) \) is defined by

\[
\hat{A}(\hat{z}) = \log \left[ \sqrt{1 - 2\hat{\rho} \hat{\sigma}^2 \hat{\nu} \hat{\nu} z^2 + \hat{\rho}^2 \hat{\nu}^2 z^2} + \frac{1}{1 - \hat{\rho}} \right]
\]

(2.17c)

For the special case of at-the-money options, options struck at \( K = \hat{f} \), this formula reduces to

\[
\hat{\sigma}_{\text{ATM}} = \hat{\sigma}(\hat{f}, \hat{f}) = \frac{\hat{\sigma}}{\hat{\A}} [1 + \frac{\hat{\sigma}^2}{24} \hat{\nu}^2 \hat{\nu}^2 + \cdots]
\]

(2.18)
These formulas are the main result of this paper. Although it appears formidable, the formula is explicit and only involves elementary trigonometric functions. Implementing the SABR model for vanilla options is very easy, since once this formula is programmed, we just need to send the options to a Black price. In the next section we examine the qualitative behavior of this formula, and how it can be used to managing smile risk.

The complexity of the formula is needed for accurate pricing. Omitting the last line of (2.17a), for example, can result in a relative error that exceeds three per cent in extreme cases. Although this error term seems small, it is large enough to be required for accurate pricing. The omitted terms “...” are much, much smaller. Indeed, even though we have derived more accurate expressions by continuing the perturbation expansion to higher order, (2.17a – 2.17c) is the formula we use to value and hedge our vanilla swaptions, caps, and floors. We have not implemented the higher order results, believing that the increased precision of the higher order results is superfluous.

There are two special cases of note: $\beta = 1$, representing a stochastic log normal model, and $\beta = 0$, representing a stochastic normal model. The implied volatility for these special cases is obtained in the last section of Appendix B.

### 3 Managing Smile Risk

The complexity of the above formula for $\sigma_{\nu}(K, f)$ obscures the qualitative behavior of the SABR model. To make the model’s phenomenology and dynamics more transparent, note that formula (2.17a – 2.17c) can be approximated as

$$
\sigma_{\nu}(K, f) = \frac{\nu}{f} \left[ 1 - \frac{1}{2} f \frac{\beta}{\nu} \log K/f \right]^{\beta - 1},
$$

(3.1a)

provided that the strike $K$ is not too far from the current forward $f$. Here the ratio

$$
\lambda = \frac{\beta f}{\nu},
$$

(3.1b)

measures the strength $\nu$ of the volatility of volatility (the “volvol”) compared to the local volatility $a(f)^{\nu}$ at the current forward. Although equations (3.1a–3.1b) should not be used to price real deals, they are accurate enough to depict the qualitative behavior of the SABR model faithfully.

As $f$ varies during normal trading, the curve that the ATM volatility $\sigma_{\nu}(K, f)$ traces is known as the backbone, while the smile and skew refer to the implied volatility $\sigma_{\nu}(K, f)$ as a function of strike $K$ for a fixed $f$. That is, the market smile/skew gives a snapshot of the market prices for different strikes $K$ at a given instance, when the forward $f$ has a specific price. Figures 3.1 and 3.2 show the dynamics of the smile/skew predicted by the SABR model.

Let us now consider the implied volatility $\sigma_{\nu}(K, f)$ in detail. The first factor $a(f)^{\nu}$ in (3.1a) is the implied volatility for at-the-money (ATM) options, options whose strike $K$ equals the current forward $f$. So the backbone traversed by ATM options is essentially $\sigma_{\nu}(S, f) = a(f)^{\nu}$ for the SABR model.

The backbone is almost entirely determined by the exponent $\beta$, with the exponent $\beta = 0$ (a stochastic Gaussian model) giving a steeply downward sloping backbone, and the exponent $\beta = 1$ giving a nearly flat backbone.

The second term $-\frac{1}{2} \log K/f$ represents the skew, the slope of the implied volatility with respect to the strike $K$. The $-\frac{1}{2} \log K/f$ part is the beta skew, which is downward sloping since $0 \leq \beta \leq 1$. It arises because the “local volatility” $\hat{\sigma} f/\sqrt{\nu}$ is a decreasing function of the forward price. The second part $\frac{1}{2} \log K/f$ is the convex skew, the skew caused by the correlation between the volatility and the asset price. Typically the volatility and asset price are negatively correlated, so on average, the volatility $\sigma$ would decrease (increase) when the forward $f$ increases (decreases). It thus seems unsurprising that a negative correlation $\rho$ causes a downward sloping vanna skew.

It is interesting to compare the skew to the slope of the backbone. As $f$ changes to $f'$ the ATM vol changes to...
Near \( K = f \), the \( \beta \) component of skew expands as

\[
\sigma_\beta(K, f) = \frac{\alpha}{f^\rho} \left(1 - \frac{\lambda^\beta}{f^\beta K} + \ldots \right).
\]  

(3.2b)

so the slope of the backbone \( \sigma_\beta(f, f') \) is twice as steep as the slope of the smile \( \sigma_\beta(K, f) \) due to the \( \beta \)-component of the skew.

The last term in (3.1a) also contains two parts. The first part \( \frac{\lambda^\beta}{f^\beta K} \) appears to be a smile (quadratic) term, but it is dominated by the downward sloping beta skew, and, at reasonable strikes \( K \), it just modifies this skew somewhat. The second part \( \frac{\lambda^\beta}{f^\beta K} \) is the smile induced by the \( \sigma_{\text{vol}} \) (vol-gamma) effect. Physically this smile arises because of “adverse selection”: unusually large movements of the forward \( f \) happen more often when the volatility \( \sigma \) increases, and less often when \( \sigma \) decreases, so strikes \( K \) far from the money represent, on average, high volatility environments.

3.1 Fitting market data. The exponent \( \beta \) and correlation \( \rho \) affect the volatility smile in similar ways. They both cause a downward sloping skew in \( \sigma(f, f') \) as the strike \( f' \) varies. From a single market snapshot of \( \sigma(f, f') \) as a function of \( f \) at a given \( f' \), it is difficult to distinguish between the two parameters. This is demonstrated by figure 3.3. There we fit the SABR parameters \( \alpha, \rho, \nu \) with \( \beta = 0 \) and then re-fit the parameters \( \alpha, \rho, \nu \) with \( \beta = 1 \). Note that there is no substantial difference in the quality of the fits, despite the presence of market noise. This matches our general experience: market smiles can be fit equally well with any specific value of \( \beta \). In particular, \( \beta \) cannot be determined by fitting a market smile since this would clearly amount to “fitting the noise.”

Figure 3.3 also exhibits a common data quality issue. Options with strikes \( K \) away from the current forward \( f \) trade less frequently than at-the-money and near-the-money options. Consequently, as \( K \) moves away from \( f \), the volatility quotes become more suspect because they are more likely to be out-of-date and not represent bona fide offers to buy or sell options.

Suppose for the moment that the exponent \( \beta \) is known or has been selected. Taking a snapshot of the market yields the implied volatility \( \sigma(f, f') \) as a function of the strike \( K \) at the current forward price \( f \). With \( \beta \) given, fitting the SABR model is a straightforward procedure. The three parameters \( \alpha, \rho, \nu \) have different effects on the curve: the parameter \( \alpha \) mainly controls the overall height of the curve, changing the correlation \( \rho \) controls the curve’s skew, and changing the vol of vol \( \nu \) controls how much smile the curve exhibits. Because of the widely-separated roles these parameters play, the fitted parameter values tend to be very stable, even in the presence of large amounts of market noise.

The exponent \( \beta \) can be determined from historical observations of the “backbone” or selected from “aesthetic considerations.” Equation (2.18) shows that the implied volatility of ATM options is

\[
\log \sigma_{\text{ATM}}(f) = \log\frac{1}{(1 - \beta) f} + \log \frac{2}{\nu \beta} + \frac{1}{24} \left\{ \alpha^2 + 2 - 3 \nu^2 \right\} \text{Implied vol} + \ldots
\]  

(3.3)

The exponent \( \beta \) can be extracted from a log log plot of historical observations of \( f / \sigma_{\text{ATM}} \) pairs. Since both \( f \) and \( \sigma \) are stochastic variables, this fitting procedure can be quite noisy, and as the \( \frac{1}{|\cdot|} \) term is typically less than one or two per cent, it is usually ignored in fitting \( \beta \).

Selecting \( \beta \) from “aesthetic” or other a priori considerations usually results in \( \beta = 0 \) (stochastic lognormal), \( \beta = \frac{1}{2} \) (stochastic normal), or \( \beta = \frac{1}{3} \) (stochastic CIR) models. Proponents of \( \beta = 1 \) cite log normal models as being “more natural.” or believe that the horizontal backbone best represents their market. These proponents often include desks trading foreign exchange options. Proponents of \( \beta = 0 \) usually believe that a normal model, with its symmetric break-even points, is a more effective tool for managing risks, and would claim that \( \beta = 0 \) is essential for trading markets like yen interest rates, where the forwards \( f \) can be negative or near zero. Proponents of \( \beta = \frac{1}{2} \) are usually US interest rate desks that have developed trust in CIR models.

It is usually more convenient to use the at-the-money volatility \( \sigma_{\text{ATM}} \), \( \rho \), and \( \nu \) as the SABR parameters instead of the original parameters \( \alpha, \beta, \nu \). The parameter \( \nu \) is then found whenever needed by inversion (2.18) on the fly; this inversion is numerically easy since the \( \frac{1}{|\cdot|} \) term is small. With this parameterization, fitting the SABR model requires fitting \( \alpha \) and \( \nu \) to the implied volatility curve, with \( \sigma_{\text{ATM}} \) and \( \beta \) given. In many markets, the ATM volatilities need to be updated frequently, say once or twice a day, while the smiles and skews need to be...
updated infrequently, say once or twice a month. With the new parameterization, $\sigma_{ATM}$ can be updated as often as needed, with $\rho$, $\nu$ (and $\beta$) updated only as needed.

Let us apply SABR to options on US dollar interest rates. There are three key groups of European options on US rates: Eurodollar future options, caps/floors, and European swaptions. Eurodollar future options are exchange-traded options on the 3 month Libor rate; like interest rate futures, EDF options are quoted on $100(1 - r_{Libor})$. Figure 1.1 fits the SABR model (with $\beta = 1$) to the implied volatility for the June 99 contracts, and figures 3.4–3.7 fit the model (also with $\beta = 1$) to the implied volatility for the September 99, December 99, and March 00 contracts. All prices were obtained from Bloomberg Information Services on March 23, 1999. Two points are shown for the same strike where there are quotes for both puts and calls. Note that market liquidity dries up for the later contracts, and for strikes that are too far from the money. Consequently, more market noise is seen for these options.

Caps and floors are sums of caplets and floorlets; each caplet and floorlet is a European option on the 3 month Libor rate. We do not consider the cap/floor market here because the broker-quoted cap prices must be “stripped” to obtain the caplet volatilities before SABR can be applied.

A $m$ year into $n$ year swaption is a European option with $m$ years to the exercise date (the maturity); if it is exercised, then one receives an $n$ year swap (the tenor, or underlying) on the 3 month Libor rate. See Appendix A. For almost all maturities and tenors, the US swaption market is liquid for at-the-money swaptions, but is ill-liquid for swaptions struck away from the money. Hence, market data is somewhat suspect for swaptions that are not struck near the money. Figures 3.8–3.11 fits the SABR model (with $\beta = 1$) to the prices of $m$ into $n$ swaptions observed on April 28, 2000. Data supplied courtesy of Cantor Fitzgerald.

We observe that the smile and skew depend heavily on the time-to-exercise for Eurodollar future options and swaptions. The smile is pronounced for short-dated options and flattens for longer dated options; the skew is overwhelmed by the smile for short-dated options, but is important for long-dated options. This picture is confirmed tables 3.1 and 3.2. These tables show the values of the vol of vol $\nu$ and correlation $\rho$ obtained by fitting the smile and skew of each “$m$ into $n$” swaption, again using the data from April 28, 2000. Note that the vol of vol $\nu$ is very high for short dated options, and decreases as the time-to-exercise increases, while the correlations starts near zero and becomes substantially negative. Also note that there is little dependence of the market skew/smile on the length of the underlying swap; both $\nu$ and $\rho$ are fairly constant across each row. This matches our general experience: in most markets there is a strong smile for short-dated options which relaxes as the time-to-expiry increases; consequently the volatility of volatility $\nu$ is large for short dated options and smaller for long-dated options, regardless of the particular underlying. Our experience with correlations is less clear: in some markets a nearly flat skew for short maturity options develops into a strongly downward sloping skew for longer maturities. In other markets there is a strong downward skew for all option maturities, and in still other markets the skew is close to zero for all maturities.
3.2. Managing smile risk. After choosing $\beta$ and fitting $\nu$, $\rho$, and either $\alpha$ or $\sigma_{ATM}$, the SABR model

$$d\hat{F} = \hat{\alpha} \hat{F}^\beta dW_1, \quad \hat{\alpha}(0) = f$$

$$d\hat{\alpha} = \nu \hat{\alpha} dW_2, \quad \hat{\alpha}(0) = \alpha$$

with

$$dW_1 dW_2 = \rho dt$$

fits the smiles and skews observed in the market quite well, especially considering the quality of price quotes away from the money. Let us take for granted that it fits well enough. Then we have a single, self-consistent model that fits the option prices for all strikes $K$ without “adjustment,” so we can use this model to price exotic options without ambiguity. The SABR model also predicts that whenever the forward price $f$ changes, the the implied volatility curve shifts in the same direction and by the same amount as the price $f$. This predicted dynamics of the smile matches market experience. If $\beta < 1$, the “backbone” is downward sloping, so the shift in the implied volatility curve is not purely horizontal. Instead, this curve shifts up and down as the at-the-money point traverses the backbone. Our experience suggests that the parameters $\nu$ and $\rho$ are very stable ($\beta$ is assumed to be a given constant), and need to be re-fit only every few weeks. This stability may be because the SABR model reproduces the usual dynamics of smiles and skews. In contrast, the at-the-money volatility $\sigma_{ATM}$, or, equivalently, $\alpha$ may need to be updated every few hours in fast-paced markets.

Since the SABR model is a single self-consistent model for all strikes $K$, the risks calculated at one strike are consistent with the risks calculated at other strikes. Therefore the risks of all the options on the same asset can be added together, and only the residual risk needs to be hedged.

Let us set aside the $\Delta$ risk for the moment, and calculate the other risks. Let $BS(f, K, \sigma_B, t_0)$ be Black’s formula (2.4a–2.4c) for, say, a call option. According to the SABR model, the value of a call is

$$V_{call} = BS(f, K, \sigma_B(K, f), t_0)$$

where the volatility $\sigma_B(K, f) = \sigma_B(K, f; \alpha, \beta, \nu, \rho)$ is given by equations (2.17a–2.17c). Differentiating [footnote: In practice risks are calculated by finite differences: valuing the option at $\alpha$, re-valuing the option after
bumping the forward to $\alpha + \delta$, and then subtracting to determine the risk. This saves differentiating complex formulas such as (2.17a–2.17c), with respect to $\alpha$ yields the vega risk, the risk to overall changes in volatility:

$$\frac{\partial V_{\text{call}}}{\partial \alpha} = \frac{\partial BS}{\partial \sigma} \frac{\partial \sigma}{\partial \alpha} \left( K, f; \alpha, \beta, \rho, \nu \right)$$

(3.6)

This risk is the change in value when $\alpha$ changes by a unit amount. It is traditional to scale vega so that it represents the change in value when the ATM volatility changes by a unit amount. Since $\delta \sigma_{\text{ATM}} = \left( \frac{\partial \sigma_{\text{ATM}}}{\partial \alpha} \right) \delta \alpha$,

$$\text{vega} \equiv \frac{\partial V_{\text{call}}}{\partial \alpha} = \frac{\partial BS}{\partial \sigma} \frac{\partial \sigma}{\partial \alpha} \frac{\sigma_{\text{ATM}}(f; \alpha, \beta, \rho, \nu)}{\sigma_{\text{ATM}}(f; \alpha, \beta, \rho, \nu)} \left( \frac{\partial \sigma_{\text{ATM}}(f; \alpha, \beta, \rho, \nu)}{\partial \alpha} \right)$$

(3.7a)

where $\sigma_{\text{ATM}}(f) = \sigma_B(f, f)$ is given by (2.18). Note that to leading order,

$$\frac{\partial \sigma_B}{\partial \alpha} \approx \frac{\sigma_B}{\alpha}$$

and

$$\frac{\partial \sigma_{\text{ATM}}}{\partial \alpha} \approx \frac{\sigma_{\text{ATM}}}{\alpha},$$

so the vega risk is roughly given by

$$\text{vega} \quad \approx \quad \frac{\partial BS}{\partial \sigma} \frac{\sigma_B}{\sigma_{\text{ATM}}(f; \alpha, \beta, \rho, \nu)}.$$  

(3.7b)

Qualitatively, then, vega risks at different strikes are calculated by bumping the implied volatility at each strike $K$ by an amount that is proportional to the implied volatility $\sigma_B(f, f)$ at that strike. That is, in using equation (3.7a), we are essentially using proportional, and not parallel, shifts of the volatility curve to calculate the total vega risk of a book of options.

Since $\rho$ and $\nu$ are determined by fitting the implied volatility curve observed in the marketplace, the SABR model has risks to $\rho$ and $\nu$ changing. Borrowing terminology from foreign exchange desks, vanna is the risk to $\rho$ changing and volga (vol gamma) is the risk to $\nu$ changing:

$$\text{vanna} = \frac{\partial V_{\text{call}}}{\partial \rho} = \frac{\partial BS}{\partial \sigma} \frac{\partial \sigma}{\partial \rho} \left( K, f; \alpha, \beta, \rho, \nu \right)$$

(3.8a)

$$\text{volga} = \frac{\partial V_{\text{call}}}{\partial \nu} = \frac{\partial BS}{\partial \sigma} \frac{\partial \sigma}{\partial \nu} \left( K, f; \alpha, \beta, \rho, \nu \right)$$

(3.8b)

Vanna basically expresses the risk to the skew increasing, and volga expresses the risk to the smile becoming more pronounced. These risks are easily calculated by using finite differences on the formula for $\sigma_B$ in equations (2.17a–2.17c). If desired, these risks can be hedged by buying or selling away-from-the-money options.
The delta risk expressed by the SABR model depends on whether one uses the parameterization \( u, \beta, \rho, \nu \) or \( \sigma_{\text{adj}}, \beta, \rho, \nu \). Suppose first we use the parameterization \( u, \beta, \rho, \nu \), so that \( \sigma_{\text{adj}}(K, f) = \sigma_{\text{adj}}(K, f; u, \beta, \rho, \nu) \). Differentiating with respect to \( f \) yields the \( \Delta \) risk

\[
\Delta = \frac{\partial \sigma_{\text{adj}}}{\partial f} + \frac{\partial \sigma_{\text{adj}}}{\partial u} \left( \sigma_{\text{adj}}(K, f; u, \beta, \rho, \nu) \right) \frac{\partial u}{\partial f} \quad (3.9)
\]

The first term is the ordinary \( \Delta \) risk one would calculate from Black's model. The second term is the SABR model's correction to the \( \Delta \) risk. It consists of the Black vega times the predicted change in the implied volatility \( \sigma_{\text{adj}} \) caused by the change in the forward \( f \). As discussed above, the predicted change consists of a sideways movement of the volatility curve in the same direction (and by the same amount) as the change in the forward \( f \). In addition, if \( \beta < 1 \) the volatility curve rises and falls as the at-the-money point traverses up and down the backbone. There may also be minor changes to the shape of the skew/smile due to changes in \( f \).

Now suppose we use the parameterization \( \sigma_{\text{adj}}, \beta, \rho, \nu \). Then \( u \) is a function of \( \sigma_{\text{adj}} \) and \( f \) defined implicitly by (2.18). Differentiating (3.5) now yields the \( \Delta \) risk

\[
\Delta = \frac{\partial \sigma_{\text{adj}}}{\partial f} + \frac{\partial \sigma_{\text{adj}}}{\partial u} \left( \sigma_{\text{adj}}(K, f; u, \beta, \rho, \nu) \right) \frac{\partial u}{\partial f} \quad (3.10)
\]

The delta risk is now the risk to changes in \( f \) with \( \sigma_{\text{adj}} \) held fixed. The last term is just the change in \( u \) needed to keep \( \sigma_{\text{adj}} \) constant while \( f \) changes. Clearly this last term must just cancel out the vertical component of the backbone, leaving only the sideways movement of the implied volatility curve. Note that this term is zero for \( \beta = 1 \).

Theoretically one should use the \( \Delta \) from equation (3.9) to risk manage option books. In many markets, however, it may take several days for volatilities \( \sigma_{\text{adj}} \) to change following significant changes in the forward price \( f \). In these markets, using \( \Delta \) from (3.10) is a much more effective hedge. For suppose one uses \( \Delta \) from equation (3.9). Then, when the volatility \( \sigma_{\text{adj}} \) did not immediately change following a change in \( f \), one would have to re-mark to \( \Delta \) instead, and this re-marking would change the \( \Delta \) hedges back to their original value. This "hedging chatter" caused by market delays can be too costly.

**Appendix A. Analysis of the SABR Model**

Here we use singular perturbation techniques to price European options under the SABR model. Our analysis is based on a small volatility expansion, where we take both the volatility \( \hat{u} \) and the "volvol" \( \hat{\nu} \) to be small. To carry out this analysis in a systematic fashion, we re-write \( \hat{u} \rightarrow \epsilon \hat{u} \) and \( \hat{\nu} \rightarrow \epsilon \hat{\nu} \), and analyze

\[
\text{WILMOTT magazine}
\]
Then our pricing formula becomes

\[ p(t, f, u; t_a, F, A) = (F - f) \Phi(A - u) + \int_{t_a}^t p(t, f, u; T, F, A) \, dT, \quad (A.5) \]

we can re-write \( V(t, f, u) \) as

\[ V(t, f, u) = [f - K]^+ + \frac{1}{2} \int_t^\infty \left[ \int_{-\infty}^\infty (F - K) \, p(t, f, u; T, F, A) \, dA \, dT \right] \, dF. \quad (A.6) \]

We substitute (A.3a) for \( p \) into (A.6). Integrating the \( A \) derivatives \( e^\rho(t_0^\infty) \int_{-\infty}^\infty \) and \( \frac{1}{2} e^\rho(t_0^\infty) \int_{-\infty}^\infty \) over all \( A \) yields zero. Therefore our option price reduces to

\[ V(t, f, u) = [f - K]^+ + \frac{1}{2} \int_t^\infty \int_{-\infty}^\infty A^2 \, p(t, f, u; T, K, A) \, dA \, dT. \quad (A.7) \]

where we have switched the order of integration. Integrating by parts twice with respect to \( F \) now yields

\[ V(t, f, u) = [f - K]^+ + \frac{1}{2} e^\rho(t_0^\infty) \int_{-\infty}^\infty A^2 \, p(t, f, u; T, K, A) \, dA \, dT. \quad (A.8) \]

The problem can be simplified further by defining

\[ P(t, f, u; T, K, A) = \int_{-\infty}^\infty A^2 \, p(t, f, u; T, K, A) \, dA. \quad (A.9) \]

Then \( P \) satisfies the backward’s Kolmogorov equation [24], [25], [26]

\[ P_t + \frac{1}{2} e^\rho(t_0^\infty) \sigma^2 \, C(f) \, P_f + \rho e^\rho(t_0^\infty) \sigma^2 \, C(f) \, P_u + \frac{1}{2} e^\rho(t_0^\infty) \sigma^2 \, P_{uu} = 0, \quad \text{for } t < T \quad (A.10a) \]

\[ P = a^2 K(f - K), \quad \text{for } t = T. \quad (A.10b) \]

Since \( t \) does not appear explicitly in this equation, \( P \) depends only on the combination \( T - t \), and not on \( t \) and \( T \) separately. So define

\[ t = T - t_a, \quad x_a = t_a - t. \quad (A.11) \]

Then our pricing formula becomes

\[ V(t, f, u) = [f - K]^+ + \frac{1}{2} e^\rho(t_0^\infty) \int_{-\infty}^\infty P(t, f, u; K) \, dK. \quad (A.12) \]

where \( P(t, f, u; K) \) is the solution of the problem

\[ P_t + \frac{1}{2} e^\rho(t_0^\infty) \sigma^2 \, C(f) \, P_f + \rho e^\rho(t_0^\infty) \sigma^2 \, C(f) \, P_u + \frac{1}{2} e^\rho(t_0^\infty) \sigma^2 \, P_{uu} = 0, \quad \text{for } t > 0. \quad (A.13a) \]

\[ P = a^2 K(f - K), \quad \text{for } t = 0. \quad (A.13b) \]

In this appendix we solve (A.13a), (A.13b) to obtain \( P(t, f, u; K) \), and then substitute this solution into (A.12) to obtain the option value \( V(t, f, u) \). This yields the option price under the SABR model, but the resulting formulas are awkward and not very useful. To cast the results in a more usable form, we re-compute the option price under the normal model

\[ d\tilde{F} = \sigma \, dW \quad (A.14a) \]

and then equate the two prices to determine which normal volatility \( \sigma \) needs to be used to reproduce the option’s price under the SABR model. That is, we find the “implied normal volatility” of the option under the SABR model. By doing a second comparison between option prices under the log normal model

\[ d\tilde{F} = \sigma \, dW \quad (A.14b) \]

and the normal model, we then convert the implied normal volatility to the usual implied lognormal (Black-Scholes) volatility. That is, we quote the option price predicted by the SABR model in terms of the option’s implied volatility.

**A.1 Singular perturbation expansion.** Using a straightforward perturbation expansion would yield a Gaussian density to leading order,\n
\[ P = a \sqrt{2 \pi \sigma^2 C(K) T} e^{-\frac{1}{2} \sigma^2 C(K) T} \quad (A.15a) \]

Since the “\( + \cdots \)” involves powers of \( (f - K)/\sigma C(K) \), this expansion would become inaccurate as soon as \( (f - K)/\sigma C(K) \) becomes a significant fraction of 1; i.e., as soon as \( C(f) \) and \( C(K) \) are significantly different. Stated differently, small changes in the exponent cause much greater changes in the probability density. A better approach is to re-cast the series as

\[ P = a \sqrt{2 \pi \sigma^2 C(K) T} e^{-\frac{1}{2} \sigma^2 C(K) T^{1+\cdots}} \quad (A.15b) \]

and expand the exponent. Since one expects that only small changes to the exponent will be needed to effect the much larger changes in the density. This expansion also describes the basic physics better. —-
Suppose we define the new variable $G$.

Then

$$\frac{(f - K)^2}{2\theta^2} \Gamma (1 + \cdots) = \frac{1}{2\theta} \left( \frac{1}{\Gamma} \int f \frac{df}{\Gamma(f)} \right)^2 (1 + \cdots). \quad (A.16)$$

Suppose we define the new variable

$$z = \frac{1}{\Gamma} \int f \frac{df}{\Gamma(f)} \quad (A.17)$$

so that the solution $P$ is essentially $e^{-z^2}$. To leading order, the density is Gaussian in the variable $z$, which is determined by how "easy" or "hard" it is to diffuse from $K$ to $f$, which closely matches the underlying physics. The fact that the Gaussian changes by orders of magnitude as $z^2$ increases should be largely irrelevant to the quality of the expansion. This approach is directly related to the geometric optics technique that is so successful in wave propagation and quantum electronics [27], [22].

To be more specific, we shall use the near identity transform method to carry out the geometric optics expansion. This method, pioneered in [28], transforms the problem order-by-order into a simple canonical problem, which can then be solved trivially. Here we obtain the solution only through $\Omega(\tau^2)$, truncating all higher order terms.

Let us change variables from $f$ to

$$z = \frac{1}{\Gamma} \int f \frac{df}{\Gamma(f)} \quad (A.18a)$$

and to avoid confusion, we define

$$R(\alpha z) = C(f). \quad (A.18b)$$

Then

$$\frac{\partial}{\partial f} \rightarrow \frac{1}{\Gamma C(f)} \frac{\partial}{\partial z} \quad \frac{\partial}{\partial z} \rightarrow \frac{\partial}{\partial z} \quad \frac{\partial}{\partial \alpha z} \rightarrow \frac{\partial}{\partial \alpha z} \quad \frac{\partial}{\partial \alpha} \rightarrow \frac{\partial}{\partial \alpha} \quad \frac{\partial}{\partial \alpha} \rightarrow \frac{\partial}{\partial \alpha} \quad (A.19a)$$

and

$$\frac{\partial^2}{\partial z^2} \rightarrow \frac{1}{\Gamma^2 \Gamma''(\alpha z)} \left( \frac{\partial^2}{\partial z^2} - \alpha \frac{\Gamma''(\alpha z)}{\Gamma(\alpha z)} \frac{\partial}{\partial \alpha} \right). \quad (A.19b)$$

$$\frac{\partial^2}{\partial \alpha \partial z} \rightarrow \frac{1}{\Gamma \Gamma(\alpha z)} \left[ \frac{\partial^2}{\partial \alpha^2} + \alpha \frac{\partial^2}{\partial \alpha \partial z} \right]. \quad (A.19c)$$

Depending on whether the "diffusion coefficient" $C(f)$ decreases or increases.

We can refine this approach by noting that the exponent is the integral

$$\frac{(f - K)^2}{2\theta^2} \Gamma (1 + \cdots)$$

and to avoid confusion, we define

$$z \quad (A.19d)$$

Also,

$$\hat{A}(f - K) = \hat{A} \Gamma(\alpha z) \quad (A.19e)$$

Therefore, (A.12) through (A.13b) become

$$V(t, f, a) = [f - K]^+ + \frac{1}{2} B^2(K) \int_0^t \hat{P}(t, z, a) \, dt, \quad (A.20)$$

where $P(t, z, a)$ is the solution of

$$P_t = \frac{1}{2} \left( 1 - 2\nu \nu_z + \hat{e} \nu \nu_z \right) P_{\nu_\nu} - \frac{1}{2} \hat{e} \nu \nu_z P_{\nu_z} + \nu (\nu - \hat{e} \nu \nu_z) P_{\nu_\nu} - P_{\nu_z}$$

$$+ \frac{1}{2} \hat{e} \nu \nu_z P_{\nu_\nu} \quad \text{for } t > 0 \quad (A.21a)$$

Accordingly, let us define $\hat{P}(t, z, a)$ by

$$\hat{P} = \frac{1}{\hat{B}(K)} \hat{A}(z) P. \quad (A.22)$$

In terms of $\hat{P}$, we obtain

$$V(t, f, a) = [f - K]^+ + \frac{1}{2} \hat{A}(K) \int_0^t \hat{P}(t, z, a) \, dt, \quad (A.23)$$

where $\hat{P}(t, z, a)$ is the solution of

$$\hat{P}_t = \frac{1}{2} \left( 1 - 2\nu \nu_z + \hat{e} \nu \nu_z \right) \hat{P}_{\nu_\nu} - \frac{1}{2} \hat{e} \nu \nu_z \hat{P}_{\nu_z} + \nu (\nu - \hat{e} \nu \nu_z) \hat{P}_{\nu_\nu}$$

$$+ \frac{1}{2} \hat{e} \nu \nu_z \hat{P}_{\nu_\nu} \quad \text{for } t > 0, \quad (A.24a)$$

To leading order $\hat{P}$ is the solution of the standard diffusion problem

$$\hat{P}_t = \frac{1}{2} \hat{P}_{\nu_\nu} \quad \text{for } t = 0. \quad (A.24b)$$

So it is a Gaussian to leading order. The next stage is to transform the problem to the standard diffusion problem through $\Omega(t)$, and then through $\Omega(\nu^2), \ldots$. This is the near identity transform method which has proven so powerful in near-Hamiltonian systems [28].
Note that the variable \( u \) does not enter the problem for \( \hat{H} \) until \( \partial \alpha / \partial t \), so
\[
P(t, z, u) = \bar{P}_z(t, z) + \bar{P}_t(t, z, u) + \cdots \quad (A.25)
\]
Consequently, the derivatives \( \bar{P}_z, \bar{P}_t, \) and \( \bar{P}_u \) are all \( \partial \alpha / \partial t \). Recall that we are only solving for \( \hat{H} \) through \( \partial \alpha / \partial t \). So, through this order, we can rewrite our problem as
\[
\hat{P}_t = \frac{1}{2} \left( 1 - 2\epsilon \alpha + \epsilon^2 \alpha^2 \right) \hat{P}_z - \frac{1}{2} \epsilon \frac{B}{B_0} \hat{P}_u + \epsilon \rho \nu \alpha \hat{P}_u \quad \text{for } \tau > 0
\]
\[
\bar{P}^* = 3 \hat{P}(z) \quad \text{at } \tau = 0. \quad (A.26a)
\]
Let us now eliminate the \( \frac{1}{2} \alpha B / B \hat{P}_t \) term. Define \( \bar{H}(t, z, u) \) by
\[
\hat{P} = \sqrt{\bar{H} / \bar{V}(z) \sqrt{B / B_0} \delta H} = \sqrt{\bar{H} \bar{V}(z)} \sqrt{B / B_0} \delta H.
\]
The option price now becomes
\[
\bar{V}(\alpha, u, \alpha) = \left[ \frac{1}{2} \left( \frac{B}{B_0} \right) \frac{\bar{H}_z + \epsilon \frac{B}{B_0} \bar{H}_u + \epsilon^2 \alpha \bar{H}_u}{4 \epsilon B} \right] \quad (A.28b)
\]
The last term is actually no larger than \( O(\epsilon^2) \). Thus, the last term is actually only \( O(\epsilon) \), and can be neglected since we are only working through \( O(\epsilon) \). So,
\[
\bar{H}_t = \frac{1}{2} \left( 1 - 2\epsilon \alpha + \epsilon^2 \alpha^2 \right) \bar{H}_z - \frac{1}{2} \epsilon \frac{B}{B_0} \bar{H}_u - \frac{1}{2} \epsilon \frac{B}{B_0} \bar{H}_u (2\hat{H}_u - \bar{H})
\]
\[
+ \epsilon^2 \alpha \left( \frac{1}{4} \frac{B}{B_0} - \frac{3 \bar{B}^2}{2 B^2} \right) \bar{H} \quad \text{for } \tau > 0
\]
\[
A(31a)
\]
There are no longer any \( u \) derivatives, so we can now treat \( u \) as a parameter instead of an independent variable. That is, we have succeeded in effectively reducing the problem to one dimension.

Let us now remove the \( \bar{H}_t \) term through \( O(\epsilon^2) \). To leading order, \( \bar{V}(\alpha, u) / \bar{H}(\alpha, u) \) and \( \bar{V}(\alpha, u) / \bar{H}(\alpha, u) \) are constant. We can replace these ratios by
\[
b_1 = \bar{V}(\alpha, u_1) / \bar{H}(\alpha, u_1), \quad b_2 = \bar{V}(\alpha, u_2) / \bar{H}(\alpha, u_2).
\]
commuting only an \( \alpha \) error, where the constant \( u_0 \) will be chosen later. We now define \( \hat{H} \) by
\[
\hat{H} = e^{b_1 \alpha} \mu(z, \alpha \hat{H}). \quad (A.29)
\]
Then our option price becomes
\[
\hat{V}(\alpha, u, \alpha) = \left[ \frac{1}{2} \left( \frac{B}{B_0} \right) \frac{b_2 \bar{H}_z + \epsilon \frac{B}{B_0} b_1 \bar{H}_u + \epsilon^2 \alpha \bar{H}_u}{4 \epsilon B} \right] \int_0^x \hat{H}(t, z) d\tau.
\]
The option price now becomes
\[
\hat{V}(\alpha, u, \alpha) = \left[ \frac{1}{2} \left( \frac{B}{B_0} \right) \frac{b_2 \bar{H}_z + \epsilon \frac{B}{B_0} b_1 \bar{H}_u + \epsilon^2 \alpha \bar{H}_u}{4 \epsilon B} \right] \int_0^x \hat{H}(t, z) d\tau.
\]
where \( \bar{H} \) is the solution of
\[
\bar{H}_t = \frac{1}{2} \left( 1 - 2\epsilon \alpha + \epsilon^2 \alpha^2 \right) \bar{H}_z - \frac{1}{2} \epsilon \frac{B}{B_0} \bar{H}_u - \frac{1}{2} \epsilon \frac{B}{B_0} \bar{H}_u (2\hat{H}_u - \bar{H})
\]
\[
+ \epsilon^2 \alpha \left( \frac{1}{4} \frac{B}{B_0} - \frac{3 \bar{B}^2}{2 B^2} \right) \bar{H} \quad \text{for } \tau > 0
\]
\[
A(32a)
\]
\[
A(32b)
\]
We’ve almost been able to take the equation into shape. We now define
\[
x = \int_0^x \frac{\epsilon^2 \alpha \bar{H}_z + \epsilon \frac{B}{B_0} b_1 \bar{H}_u + \epsilon^2 \alpha \bar{H}_u}{4 \epsilon B} \int_x^\infty \frac{d\tau}{\sqrt{1 - 2\epsilon \alpha + \epsilon^2 \alpha^2}}
\]
\[
A(34a)
\]
\[
A(35a)
\]
\[
A(36a)
\]
which can be written implicitly as
\[
e\alpha v z = \sinh e \alpha v z - \epsilon (\cosh e \alpha v z - 1).
\]
\[
A(36b)
\]
In terms of $x$, our problem is

\[ V(t, f, a) = [f - K]^+ + \frac{1}{2} \left( \frac{a}{\sigma_f^2} \right) \tilde{H} \left( \tilde{u}_e(x) \right) e^{\nu_1 \nu_2 x} \int_0^x \tilde{H}(t, x') \, dx' \]  \hspace{1cm} \text{(A.37)}

with

\[ \tilde{H}_t = \frac{1}{2} \tilde{H}_{xx} - \frac{1}{2} e^{\nu_1 \nu_2 x} \tilde{H}_x + e^{\nu_1 \nu_2 x} \left( \frac{1}{2} \gamma_0 - \frac{3}{4} \nu_2 \right) \tilde{H} + \frac{3}{4} e^{\nu_1 \nu_2 x} \rho a h \tilde{H} \]  \hspace{1cm} \text{for } t > 0

(\text{A.38a})

and

\[ \tilde{H} = \tilde{h}(x) \text{ at } t = 0. \]  \hspace{1cm} \text{A.38b}

Here

\[ \tilde{h}(x) = \sqrt{1 - 2e^x + \xi^2}. \]  \hspace{1cm} \text{A.39}

The final step is to define $Q$ by

\[ \tilde{H} = \tilde{h}^{(1/2)}(x) \left[ Q_0 + \frac{1}{2} e^{\nu_1 \nu_2 x} \tilde{H}_0 \right]. \]  \hspace{1cm} \text{A.40a}

Then

\[ \tilde{H}_t = \tilde{h}^{(1/2)}(x) \left[ Q_0_e + \frac{1}{2} e^{\nu_1 \nu_2 x} \tilde{H}_0 + e^{\nu_1 \nu_2 x} \left( \frac{1}{2} \gamma_0 + \frac{3}{4} \rho a h \right) \tilde{H} \right], \]  \hspace{1cm} \text{A.41a}

and so

\[ V(t, f, a) = [f - K]^+ + \frac{1}{2} (\sqrt{\sigma_f^2 + R(a)^2}) \tilde{h}^{(1/2)}(x) e^{\nu_1 \nu_2 x} \int_0^x \tilde{H}(t, x') \, dx' \]  \hspace{1cm} \text{A.42a}

where $Q_0$ is the solution of

\[ Q_0 = \frac{1}{2} Q_0 + e^{\nu_1 \nu_2 x} \left( \frac{1}{4} \gamma_0 - \frac{1}{4} \gamma_0 + \frac{3}{4} \rho a h \right) \tilde{H} + \frac{3}{4} e^{\nu_1 \nu_2 x} \rho a h \tilde{H} \]  \hspace{1cm} \text{A.43a}

for $t > 0$, with

\[ Q_0 = \tilde{h}(x) \text{ at } t = 0. \]  \hspace{1cm} \text{A.43b}

As above, we can replace $I(u, v, f_{u(v, 2)}, f'_{u(v, 2)})$ by the constants $I(u(v, 2), f_{u(v, 2)}, f'_{u(v, 2)})$, and commit only $\tilde{h}(x)$ errors. Define the constant $k$ by

\[ k = e^{\nu_1 \nu_2 x} \tilde{h}(x) \tilde{h}(x) - \frac{1}{2} \left( f_{u(v, 2)} \right)^2 \]  \hspace{1cm} \text{A.44}

where $k_0$ will be chosen later. Then through $O(e^k)$, we can simplify our equation to

\[ Q_0 = \frac{1}{2} Q_0 + e^k \frac{1}{2} \tilde{h}(x) \]  \hspace{1cm} \text{A.45a}

\[ Q = \tilde{h}(x) \text{ at } t = 0. \]  \hspace{1cm} \text{A.45b}

The solution of A.45a, A.45b is clearly

\[ Q = \frac{1}{\sqrt{2\pi e^k}} e^{-e^k/e^k} = \frac{1}{\sqrt{2\pi e^k}} e^{-e^k/[1 - (1/4)e^k]} \]  \hspace{1cm} \text{A.46}

through $O(e^k)$. This solution yields the option price

\[ V(t, f, a) = [f - K]^+ + \frac{1}{2} \left( \sqrt{\sigma_f^2 + R(a)^2} \right) \tilde{h}^{(1/2)}(x) e^{\nu_1 \nu_2 x} \int_0^x \tilde{H}(t, x') \, dx' \]  \hspace{1cm} \text{A.47}

Observe that this can be written as

\[ V(t, f, a) = [f - K]^+ + \frac{1}{2} \frac{f - K}{x} \int_0^x \frac{1}{2} e^{\nu_1 \nu_2 x} e^k \, dx', \]  \hspace{1cm} \text{A.48a}

where

\[ e^k \theta = \log \left( \frac{e^k}{x} \right) + \log \left( \frac{\tilde{h}^{(1/2)}(x)}{\tilde{h}(x)} \right) + \frac{1}{4} \rho a h \tilde{h}. \]  \hspace{1cm} \text{A.48b}

Moreover, quite amazingly,

\[ e^k \theta = \frac{1}{1 - (1/4)e^k} + O(e^k), \]  \hspace{1cm} \text{A.48c}

through $O(e^k)$. This can be shown by expanding $e^k$ through $O(e^k)$, and noting that $e^k / x^2$ matches $A/3$. Therefore our option price is

\[ V(t, f, a) = [f - K]^+ + \frac{1}{2} \frac{f - K}{x} \int_0^x \frac{1}{2} e^{\nu_1 \nu_2 x} \tilde{h} \, dx \]  \hspace{1cm} \text{A.49}

and changing integration variables to

\[ q = e^k \frac{1}{2\tilde{h}} \]  \hspace{1cm} \text{A.50}

reduces this to

\[ V(t, f, a) = [f - K]^+ + \frac{1}{2} \frac{f - K}{x} \int_0^x e^{\nu_1 \nu_2 x} \frac{1}{2\tilde{h}} \, dq \]  \hspace{1cm} \text{A.51}
That is, the value of a European call option is given by

\[ V(t, f, a) = (f - K)_+ + \frac{(f - K)}{4} \int_0^\infty \frac{e^x}{
\sqrt{2\pi x}} dx \]  \hspace{1cm} (A.52a)

with

\[ e^x = \log \left( \frac{4a^2}{\sqrt{\pi \nu\tau}} \right) \quad \text{and} \quad \int_0^\infty \frac{e^x}{
\sqrt{2\pi x}} dx = \frac{1}{\sqrt{\nu\tau}} \]

through \( \alpha(x) \).

A.2. Equivalent normal volatility. Equations (A.52a) and (A.52a) are a formula for the dollar price of the call option under the SABR model. The utility and beauty of this formula is not overwhelmingly apparent. To obtain a useful formula, we convert this dollar price into the equivalent implied volatilities. We first obtain the implied normal volatility, and then the standard log normal (Black) volatility.

Suppose we repeated the above analysis for the ordinary normal model

\[ d\tilde{F} = \sigma_\text{e} dW, \quad R(t) = f. \]  \hspace{1cm} (A.53a)

where the normal volatility \( \sigma_\text{e} \) is constant, not stochastic. (This model is also called the absolute or Gaussian model). We would find that the option value for the normal model is exactly

\[ V(t, f) = (f - K)_+ + \frac{(f - K)}{4} \int_0^\infty \frac{e^x}{
\sqrt{2\pi x}} dx \]  \hspace{1cm} (A.53b)

This can be seen by setting \( C(f) \) to 1, setting \( \sigma \) to \( \sigma_\text{e} \), and setting \( \nu \) to 0 in A.52a, A.52b. Working out this integral then yields the exact European option price

\[ V(t, f) = (f - K) N\left( \frac{f - K}{\sigma_\text{e} \sqrt{\nu\tau}} \right) + \sigma_\text{e} \sqrt{\nu\tau} \phi \left( \frac{f - K}{\sigma_\text{e} \sqrt{\nu\tau}} \right), \]  \hspace{1cm} (A.54a)

for the normal model, where \( N \) is the normal distribution and \( \phi \) is the Gaussian density

\[ \phi(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}. \]  \hspace{1cm} (A.54b)

From A.53b it is clear that the option price under the normal model matches the option price under the SABR model A.52a if and only if we choose the normal volatility \( \sigma_\text{e} \) to be

\[ \frac{1}{\sigma_\text{e}^2} = \frac{x}{(f - K)^2} \left[ 1 - 2x^2 + \frac{\theta}{\tau} \right]. \]  \hspace{1cm} (A.55)

Taking the square root now shows the option’s implied normal (absolute) volatility is given by

\[ \sigma_\text{e} = \frac{f - K}{x} \left[ 1 + x^2 + \frac{\theta}{\tau} \right]. \]  \hspace{1cm} (A.56)

Before continuing to the implied log normal volatility, let us seek the simplest possible way to rewrite this answer which is correct through \( O(\alpha^2) \). Since \( x = z + (\alpha x) \), we can rewrite the answer as

\[ \sigma_\text{e} = \frac{f - K}{z} \left[ 1 + x^2 (\phi_1 + \phi_2 + \phi_3 + \ldots) \right]. \]  \hspace{1cm} (A.56a)

Through \( O(\alpha^2) \).

This factor represents the average difficulty in diffusing from today’s forward \( f \) to the strike \( K \), and would be present even if the volatility were not stochastic.

The next factor is

\[ \frac{z}{x} = \frac{\int_{-\infty}^{\infty} d\nu (\nu + K)^{-1}}{\int_{-\infty}^{\infty} d\nu (\nu + K)^{-1}} = \frac{1 + O(\alpha)}{\nu + K}. \]  \hspace{1cm} (A.57b)

Here \( \nu_c = \sqrt{K} \) is the geometric average of \( f \) and \( K \). (The arithmetic average could have been used equally well at this order of accuracy). This factor represents the main effect of the stochastic volatility.

The coefficients \( \phi_1, \phi_2, \phi_3 \) and \( \phi_4 \) provide relatively minor corrections. Through \( O(\alpha^2) \) these corrections are

\[ e^x \phi_1 = \frac{1}{2} \log \left( \frac{\nu + K}{f - K} \right) \]  \hspace{1cm} (A.57d)

\[ = \frac{2\nu}{\nu + K} \nu_c^2 C'(f_0) + \ldots \]

\[ e^x \phi_2 = \frac{1}{2} \log \left( \frac{\nu + K}{f - K} \right) \]  \hspace{1cm} (A.57e)

\[ = \frac{2\nu}{\nu + K} \nu_c^2 C'(f_0) + \ldots \]

\[ e^x \phi_3 = \frac{1}{4} \nu_c^2 \nu \phi \left( \frac{\nu + K}{f - K} \right) \]  \hspace{1cm} (A.57f)

\[ = \frac{2\nu}{\nu + K} \nu_c^2 C'(f_0) + \ldots \]

\[ \nu_1 = \frac{C'(f_0)}{C(f_0)} \quad \text{and} \quad \nu_2 = \frac{C'(f_0)}{C(f_0)} \]  \hspace{1cm} (A.57g)

Wilmott magazine
Let us briefly summarize before continuing. Under the normal model, the value of a European call option with strike \( K \) and exercise date \( t_e \) is given by (A.54a), (A.54b). For the SABR model,

\[
d\tilde{V} = \sigma \tilde{W} \tilde{d}t, \quad \tilde{d}(0) = f
\]

(A.58a)

\[
d\tilde{W} = \rho \tilde{d}t, \quad \tilde{d}(0) = a
\]

(A.58b)

\[
dW_1dW_2 = \rho dt
\]

(A.58c)

the value of the call option is given by the same formula, at least through \( \alpha x^2 \), provided we use the implied normal volatility

\[
\sigma_x(K) = \frac{\alpha K \sqrt{f - K}}{\sqrt{2\pi}} \left( \frac{x}{\sqrt{f}} \right)
\]

(A.59a)

\[
\left\{ 1 + \frac{2\gamma - 2\alpha^2}{24} x^2(C(f)) + \frac{1}{4} \rho \sigma_x \Gamma(C(f)) \right\}
\]

(A.59b)

\[
\left\{ 1 + \frac{2\gamma - 2\alpha^2}{24} x^2(C(f)) \right\} x \tau_a + \ldots
\]

(A.59c)

Here

\[
f_v = \sqrt{f}, \quad \gamma_1 = C'(f)/(C(f)), \quad \gamma_2 = C''(f)/(C(f))
\]

(A.59d)

\[
\tilde{d}(\tilde{\tau}) = \log \left( \frac{\sqrt{1 - 2\rho x + x^2} + \rho + \tilde{\tau} - \xi}{1 - \rho} \right)
\]

(A.59e)

The first two factors provide the dominant behavior; with the remainder factor \( 1 + \ldots \) \( x^2 \tau_a \), usually providing corrections of around 1\% or so. One can repeat the analysis for a European put option, or simply use call/put parity. This shows that the value of the put option under the SABR model is

\[
V_{\text{put}}(f, K, \tau) = (K - f) N \left( \frac{K - f}{\sigma_x \sqrt{\tau}} \right) + \sigma_x \sqrt{\tau} \left( \frac{K - f}{\sigma_x \sqrt{\tau}} \right) + \ldots
\]

(A.59f)

where the implied normal volatility \( \sigma_x \) is given by the same formulas (A.59a - A.59c) as the call.

We can revert to the original units by replacing \( \alpha \rightarrow \alpha \), \( \tau_a \rightarrow \tau \) everywhere in the above formulas; this is equivalent to setting \( \varepsilon \rightarrow 1 \) everywhere.

**A. 3. Equivalent Black vol.** With the exception of JPY traders, most traders prefer to quote prices in terms of Black (log normal) volatilities, rather than normal volatilities. To derive the implied Black volatility, consider Black’s model

\[
d\tilde{V} = \varepsilon \sigma \tilde{W}, \quad \tilde{d}(0) = f
\]

(A.61)

where we have written the volatility as \( \varepsilon \sigma \) to stay consistent with the preceding analysis. For Black’s model, the value of a European call with strike \( K \) and exercise date \( t_e \) is

\[
V_{\text{call}} = f N(d_1) - K N(d_2)
\]

(A.62a)

\[
V_{\text{call}} = f + D(t_e)(K - f)
\]

(A.62b)

with

\[
d_1 = \frac{\log f + \frac{1}{2} \sigma^2 \tau}{\varepsilon \sigma \sqrt{\tau}}
\]

(A.62c)

where we are omitting the overall factor \( D(t_e) \) as before.

We can obtain the implied normal volatility for Black’s model by repeating the preceding analysis for the SABR model with \( C(f) = f \) and \( v = 0 \). Setting \( C(f) = f \) and \( v = 0 \) in (A.59d - A.59e) shows that the normal volatility is

\[
\sigma_x(K) = \frac{\alpha K \sqrt{f - K}}{\sqrt{2\pi}} \left( \frac{x}{\sqrt{f}} \right)
\]

(A.63)

through \( \alpha x^2 \). Indeed, in (14) it is shown that the implied normal volatility for Black’s model is

\[
\sigma_x(K) = \frac{\alpha K \sqrt{f - K}}{\sqrt{2\pi}} \log f
\]

(A.64)

and

\[
\sigma_x(K) = \frac{\alpha K \sqrt{f - K}}{\sqrt{2\pi}} \log f + \ldots
\]

(A.65)

through \( \alpha x^2 \). We can find the implied Black vol for the SABR model by setting \( \varepsilon = \sigma_x \) obtained from Black’s model in equation (A.63) equal to \( \varepsilon = \sigma_x \) obtained from the SABR model in (A.59d - A.59e). Through \( \alpha x^2 \) this yields

\[
\sigma_x(K) = \frac{\alpha K \sqrt{f - K}}{\sqrt{2\pi}} \left( \frac{x}{\sqrt{f}} \right)
\]

(A.66)

\[
\left\{ 1 + \frac{2\gamma - 2\alpha^2}{24} x^2(C(f)) + \frac{1}{4} \rho \sigma_x \Gamma(C(f)) \right\}
\]

(A.67)

\[
\left\{ 1 + \frac{2\gamma - 2\alpha^2}{24} x^2(C(f)) \right\} x \tau_a + \ldots
\]

(A.68)

This is the main result of this article. As before, the implied log normal volatility for puts is the same as for calls, and this formula can be re-cast in terms of the original variables by simply setting \( \varepsilon \rightarrow 1 \).
A.4. Stochastic $\beta$ model. As originally stated, the SABR model consists of the special case $C(f) = f^2$:

$$d\tilde{V} = \tilde{u} d\tilde{W}_T, \quad \tilde{W}_0 = f$$  \hspace{1cm} (A.66a)

$$d\tilde{u} = \tilde{v} d\tilde{W}_t, \quad \tilde{u}(0) = u$$  \hspace{1cm} (A.66b)

$$d\tilde{W}_t d\tilde{W}_s = \rho \tilde{u} dt.$$  \hspace{1cm} (A.66c)

Making this substitution in (A.58a–A.58b) shows that the implied normal volatility for this model is

$$\sigma_0(K) = e^{a(1-\beta)/2} \left( \frac{\xi}{a(\xi)} \right) \left[ 1 + \frac{-\beta(2-\beta)\sigma^2}{24K^{1-\beta}} + \frac{\rho \sigma \nu}{4\nu} \left( 2 - 3\sigma^2 \right) \right] t_k + \ldots$$

through $O(t^3)$, where $f_0 = \sqrt{K}$ as before and

$$\xi \equiv \frac{\sqrt{f - K}}{\nu \sigma}, \quad \hat{\beta} \equiv \log \left( \frac{\sqrt{1 - 2\sigma + \xi^2 - \rho + \zeta}}{1 - \rho} \right).$$  \hspace{1cm} (A.67b)

We can simplify this formula by expanding

$$f - K = \sqrt{a} \log f K \left[ 1 + \frac{1}{24} \log^2 f K + \frac{1}{1920} \log^3 f K + \ldots \right]$$  \hspace{1cm} (A.68a)

$$f^{1-\beta} - K^{1-\beta} = (1-\beta) f^{1-\beta} \log f K \left[ 1 + \frac{1}{24} \log^2 f K + \frac{1}{1920} \log^3 f K + \ldots \right]$$  \hspace{1cm} (A.68b)

and neglecting terms higher than fourth order. This expansion reduces the implied normal volatility to

$$\sigma_0(K) = e^{a(1-\beta)} \left[ \frac{1}{24} \log^2 f K + \frac{1}{1920} \log^3 f K + \ldots \right] \left( \frac{\xi}{\beta(1-\beta)} \right) \left[ 1 + \frac{-\beta(2-\beta)\sigma^2}{24(K)^{1-\beta}} + \frac{\rho \sigma \nu}{4\nu} \left( 2 - 3\sigma^2 \right) K^{1-\beta} \right] t_k + \ldots$$

through $O(t^3)$, where $\xi$ and $\hat{\beta}$ are given by (A.67b) as before. Apart from setting $\xi$ to 1 to recover the original units, this is the formula quoted in section 2, and fitted to the market in section 3.

A.5. Special cases Two special cases are worthy of special treatment: the stochastic normal model ($\beta = 0$) and the stochastic log normal model ($\beta = 1$). Both these models are simple enough that the expansion can be continued through $O(t^3)$. For the stochastic normal model ($\beta = 0$) the implied volatilities of European calls and puts are

$$\sigma_0(K) = e^{\frac{a}{\sqrt{a}}} \left( f K \right)^{1-\beta/2}$$

where

$$\xi = \frac{u}{\sqrt{a}} \log f K, \quad \hat{\beta} \equiv \log \left( \frac{\sqrt{1 - 2\sigma + \xi^2 - \rho + \zeta}}{1 - \rho} \right).$$  \hspace{1cm} (A.69b)

This is the formula we use in pricing European calls and puts.

To obtain the implied Black volatility, we equate the implied normal volatility $\sigma_0(K)$ for the SABR model obtained in (A.69a–A.69b) to the implied normal volatility for Black’s model obtained in (A.63). This shows that the implied Black volatility for the SABR model is

$$\sigma_0(K) = \frac{e^{\frac{a}{\sqrt{a}}} \left( f K \right)^{1-\beta/2}}{1 - \frac{1}{24}(1 - \beta) \nu^2} \left( \frac{\xi}{\beta(1-\beta)} \right) \left[ 1 + \frac{-\beta(2-\beta)\sigma^2}{24(K)^{1-\beta}} + \frac{\rho \sigma \nu}{4\nu} \left( 2 - 3\sigma^2 \right) K^{1-\beta} \right] t_k + \ldots$$

through $O(t^3)$, where $\xi$ and $\hat{\beta}$ are given by (A.69b) as before. Apart from setting $\xi$ to 1 to recover the original units, this is the formula quoted in section 2, and fitted to the market in section 3.
Now shows that the option price is given by
\[ P = a^2 k f - K, \text{ for } t = T. \] (B.4b)
We eliminate \( y(t) \) by defining the new time variable
\[ s = \int_{T}^{t} y^2(t') \, dt', \quad s' = \int_{T}^{s} y^2(t') \, dt'. \] (B.5)
Then the option price becomes
\[ P = a^2 k f - K, \quad \text{for } s = s'. \] (B.6)

Here
\[ \eta(t) = \rho(t) y(t)/y(t), \quad \upsilon(t) = y(t)/y(t). \] (B.8)

We solve this problem by using an effective medium strategy [23]. In this strategy our objective is to determine which constant values \( \hat{\eta} \) and \( \hat{\upsilon} \) yield the same option price as the time dependent coefficients \( \eta(t) \) and \( \upsilon(t) \). If we could find these constant values, this would reduce the problem to the non-dynamic SABR model solved in Appendix B.

We carry out this strategy by applying the same series of time-independent transformations that was used to solve the non-dynamic SABR model in Appendix B, defining the transformations in terms of the (as yet unknown) constants \( \hat{\eta} \) and \( \hat{\upsilon} \). The resulting problem is relatively complex, more complex than the canonical problem obtained in Appendix B. We use a regular perturbation expansion to solve this problem, and once we have solved this problem, we choose \( \hat{\eta} \) and \( \hat{\upsilon} \) so that all terms arising from the time dependence of \( \eta(t) \) and \( \upsilon(t) \) cancel out. As we shall see, this simultaneously determines the “effective” parameters and allows us to use the analysis in Appendix B to obtain the implied volatility of the option.

B.1 Transformation. As in Appendix B, we change independent variables to
\[ z = \frac{1}{\alpha} \int_0^H dz'/C(f'). \] (B.9a)
and define
\[ \bar{R}(\alpha z) = C(f). \] (B.9b)
We then change dependent variables from \( P \) to \( \hat{P} \), and then to \( H, \)
\[ \hat{P} = \frac{1}{\alpha} C(f) P. \] (B.9c)
where $H(t, z, x', t') = \frac{\partial}{\partial t} \tilde{H}(t, z, x', t').$

At this point we would like to use a time-independent transformation to remove the $\tilde{H}_t$ term from equation (B.13a). It is not possible to cancel this term exactly since the coefficient $\eta(t)$ is time dependent. Instead we use the transformation

$$H = e^{\xi \omega(t)} \tilde{H}_t,$$

where the constant $\xi$ will be chosen later. This transformation yields

$$\tilde{H}_t + \frac{1}{2} (1 - 2 \xi \tilde{H} + \xi^2 \tilde{H}^2) \tilde{H}_{tt} - \frac{1}{2} \eta(t) \tilde{H}_t = 0,$$

$$+ \xi \omega(t) \left( \frac{3}{4} \frac{1}{2} \frac{1}{2} \right) \tilde{H} = 0 \text{ for } s < s',$$

$$\tilde{H} = \delta(z) \text{ at } s = s'. \tag{B.13b}$$

At this point we would like to use a time-independent transformation to remove the $\tilde{H}_t$ term from equation (B.13a). It is not possible to cancel this term exactly since the coefficient $\eta(t)$ is time dependent. Instead we use the transformation

$$H = e^{\xi \omega(t)} \tilde{H}_t,$$

where the constant $\xi$ will be chosen later. This transformation yields

$$\tilde{H}_t + \frac{1}{2} (1 - 2 \xi \tilde{H} + \xi^2 \tilde{H}^2) \tilde{H}_{tt} - \frac{1}{2} \eta(t) \tilde{H}_t = 0,$$

$$+ \xi \omega(t) \left( \frac{3}{4} \frac{1}{2} \frac{1}{2} \right) \tilde{H} = 0 \text{ for } s < s',$$

$$\tilde{H} = \delta(z) \text{ at } s = s'. \tag{B.13a}$$

At this point we would like to use a time-independent transformation to remove the $\tilde{H}_t$ term from equation (B.13a). It is not possible to cancel this term exactly since the coefficient $\eta(t)$ is time dependent. Instead we use the transformation

$$H = e^{\xi \omega(t)} \tilde{H}_t,$$

where the constant $\xi$ will be chosen later. This transformation yields

$$\tilde{H}_t + \frac{1}{2} (1 - 2 \xi \tilde{H} + \xi^2 \tilde{H}^2) \tilde{H}_{tt} - \frac{1}{2} \eta(t) \tilde{H}_t = 0,$$

$$+ \xi \omega(t) \left( \frac{3}{4} \frac{1}{2} \frac{1}{2} \right) \tilde{H} = 0 \text{ for } s < s',$$

$$\tilde{H} = \delta(z) \text{ at } s = s'. \tag{B.13b}$$

At this point we would like to use a time-independent transformation to remove the $\tilde{H}_t$ term from equation (B.13a). It is not possible to cancel this term exactly since the coefficient $\eta(t)$ is time dependent. Instead we use the transformation

$$H = e^{\xi \omega(t)} \tilde{H}_t,$$

where the constant $\xi$ will be chosen later. This transformation yields

$$\tilde{H}_t + \frac{1}{2} (1 - 2 \xi \tilde{H} + \xi^2 \tilde{H}^2) \tilde{H}_{tt} - \frac{1}{2} \eta(t) \tilde{H}_t = 0,$$

$$+ \xi \omega(t) \left( \frac{3}{4} \frac{1}{2} \frac{1}{2} \right) \tilde{H} = 0 \text{ for } s < s',$$

$$\tilde{H} = \delta(z) \text{ at } s = s'. \tag{B.13a}$$

At this point we would like to use a time-independent transformation to remove the $\tilde{H}_t$ term from equation (B.13a). It is not possible to cancel this term exactly since the coefficient $\eta(t)$ is time dependent. Instead we use the transformation

$$H = e^{\xi \omega(t)} \tilde{H}_t,$$
where we can simplify this to

\[ Q + \frac{1}{2} Q_{ss} = s(q - \bar{q}) a_{Q} + \frac{1}{2} \left[ \psi^2 - \bar{\psi}^2 - 3b(q - \bar{q}) \right] Q_{ss} \]

\[ + \frac{1}{2} \alpha^2 a_{bb} (q - \bar{q}) a_{Q} \]

\[ - \frac{1}{2} \alpha^2 a_{bb} Q_{ss} - \frac{1}{2} \left( \frac{1}{4} \psi'' + \frac{1}{2} \bar{\psi}' - \frac{1}{2} \bar{\psi}' \right) Q_{ss} \]

\[ - \frac{1}{2} \alpha^2 a_{bb} \left( \frac{1}{4} b_0 - \frac{1}{8} b_2 \right) Q_{ss} \]  

for \( s < s' \), \( \text{(B.22a)} \)

\[ Q = \tilde{q}(s) \quad \text{at} \quad s = s', \]

(\text{B.22b)}

through \( \tilde{q}(s) \). Note that if \( \bar{f}, \tilde{f}' \) can be replaced by the constants \( B_{(Q_{0})}, B_{(Q_{2})} \) and \( B_{(Q_{2})} \) through \( \tilde{q}(s) \).

### 2. Perturbation expansion.

Substituting this expansion into (B.22a), (B.22b) yields the following hierarchy of equations. To leading order we have

\[ Q^{(1)} + \frac{1}{2} Q_{ss}^{(1)} = 0 \quad \text{for} \quad s < s', \quad \text{(B.24a)} \]

\[ Q^{(0)} = \tilde{q}(s) \quad \text{at} \quad s = s'. \]

(\text{B.24b)}

At \( \tilde{q}(s) \) we have

\[ Q^{(1)} + \frac{1}{2} Q_{ss}^{(1)} = (q - \bar{q}) a_{Q}^{(1)} \quad \text{for} \quad s < s', \quad \text{(B.25a)} \]

\[ Q^{(1)} = 0 \quad \text{at} \quad s = s'. \]

(\text{B.25b)}

At \( \tilde{q}(s) \) we can break the solution into

\[ Q^{(2)} = Q^{(2)} + Q^{(3)} + Q^{(4)}, \quad \text{(B.26)} \]

where

\[ Q^{(2)} + \frac{1}{2} Q_{ss}^{(2)} = - \frac{1}{2} \alpha^2 a_{bb} Q_{ss}^{(1)} - \frac{1}{2} \alpha^2 a_{bb} \left( \frac{1}{4} b_0 - \frac{1}{8} b_2 \right) Q_{ss}^{(1)} \]

\[ - \left( \frac{1}{4} b_0 - \frac{1}{8} b_2 \right) Q_{ss}^{(1)} \quad \text{for} \quad s < s', \]

\[ Q^{(2)} = 0 \quad \text{at} \quad s = s', \]

(\text{B.27a)}

\[ Q^{(3)} = Q^{(3)} + Q^{(4)} + \cdots \]

\[ \text{and, through} \quad \tilde{q}(s) \]  \( Q^{(2)} \) would be the solution of the static problem

\[ Q^{(1)} + \frac{1}{2} Q_{ss}^{(1)} = \frac{3}{4} \alpha^2 a_{bb} Q_{ss}^{(1)} - \frac{3}{4} \alpha^2 a_{bb} \left( \frac{1}{4} b_0 - \frac{1}{8} b_2 \right) Q_{ss}^{(1)} \]

\[ - \left( \frac{1}{4} b_0 - \frac{1}{8} b_2 \right) Q_{ss}^{(1)} \quad \text{for} \quad s < s', \]

\[ Q^{(2)} = \tilde{q}(s) \quad \text{at} \quad s = s'. \]

(\text{B.27b)}

This is exactly the time-independent problem solved in Appendix B. See equations (A-42), (A-43a), and (A-43b). So if we can carry out this strategy, we can obtain option prices for the dynamic SABR model by reducing them to the previously-obtained prices for the static model.
B.2.1. Leading order analysis  The solution of (B.24a), (B.24b) is Gaussian:

\[ Q^{(2)} = G(x / \Delta) \]  

(B.32a)

where

\[ G(x / \Delta) = \frac{1}{\sqrt{2\pi}\Delta} e^{-x^2 / 2\Delta} \Delta = \delta - \varepsilon \]  

(B.32b)

For future reference, note that

\[ G_{\alpha\nu} = \frac{x^2 - 2\Delta x^3}{2\Delta}, \quad G_{\alpha\nu} = \frac{x^2 - 3\Delta x^5}{2\Delta}, \]  

(B.33a)

\[ G_{\alpha\nu} = \frac{x^4 - 6\Delta x^2 + 3\Delta^2}{2\Delta^3}, \quad G_{\alpha\nu} = \frac{x^4 - 10\Delta x^2 + 15\Delta^2}{2\Delta^3}. \]  

(B.33b)

This term makes a contribution of

\[ \int Q^{(2)}(x, \varepsilon \delta') d\delta' = 2\alpha \int (\varepsilon - \delta) \delta d\delta \]  

(B.40)

to the option price, so we choose

\[ \varepsilon = \frac{1}{\sqrt{2}} \left( \frac{\Delta}{\varepsilon} \right)^{1/2} \]  

(B.41)

to eliminate this contribution.

B.2.2. Order \( \varepsilon \)  Substituting \( Q^{(2)} \) into the equation for \( Q^{(1)} \) and using (B.33a) yields

\[ Q^{(1)} + \frac{1}{2} Q^{(2)} = \frac{(\varepsilon - \delta')^2}{\Delta} \]  

(B.34)

with the "initial" condition \( Q^{(1)} = 0 \) at \( \varepsilon = \delta' \). The solution is

\[ Q^{(1)} = A(\varepsilon, \delta') G_{\alpha\nu} + 2B(\varepsilon, \delta') G_{\alpha\nu} \]  

(B.35a)

\[ A(\varepsilon, \delta') = \frac{1}{\sqrt{2\pi}} \left( 2\alpha(\varepsilon, \delta') G_{\alpha\nu}(x / \Delta) \right), \]  

(B.35b)

This term contributes

\[ \int Q^{(1)}(x, \varepsilon, \delta') d\delta' = 2\alpha A(\varepsilon, \delta') \int G_{\alpha\nu}(x / \Delta) \]  

(B.36)

This can be re-written as

\[ Q^{(2)} + \frac{1}{2} Q^{(2)} = -\frac{1}{2} \left[ \delta - \frac{1}{\alpha} \right] \delta d\delta + \frac{1}{2} \left[ \delta^2 - \frac{1}{\alpha^2} \right] + \frac{1}{2} \left[ \delta^2 - \frac{1}{\alpha^2} \right] \]  

(B.37)

This can be written as

\[ Q^{(2)} = \frac{1}{2} \delta^2 G_{\alpha\nu} + \frac{1}{2} \delta^2 G_{\alpha\nu} + 2\alpha \delta G_{\alpha\nu} \]  

(B.45)
Recall that \( \dot{\eta} \) was chosen above so that \( \kappa(t, \dot{\eta}) = 0 \). Therefore the contribution of \( Q^{(2)} \) to the option price is
\[
\int_0^T Q^{(2)}(s, \kappa \xi, \xi') \, ds = \left( -\frac{1}{2} \int_0^T \kappa(s, \dot{\eta}) \, ds \right) \left( \kappa(s, \dot{\eta}) \right)
\]
\( + \int_0^T \left[ \kappa(s, \dot{\eta}) \right] \left( \kappa(s, \dot{\eta}) \right) \, ds \),
where \( \kappa = \dot{\eta}^2 - \dot{\eta}^2 - \sigma^2 q(t) - \dot{\eta} \).

We can choose the remaining “effective parameter” \( \dot{\eta} \) to set either the coefficient of \( G_s(s, \sqrt{\dot{\eta}^2 - \sigma^2 q(t)}) \) or the coefficient of \( G_s(s, \sqrt{\dot{\eta}^2}) \) to zero, but cannot set both to zero to completely eliminate the contribution of the term \( Q^{(1)} \). We choose \( \eta \) to set the coefficient of \( G_s(s, \sqrt{\dot{\eta}^2 - \sigma^2}) \) to zero, for reasons that will become apparent in the following:
\[
\dot{\eta}^2 - \frac{1}{2} (\dot{\eta}_t - \dot{\eta}_t) \left( \int_0^T (\dot{\eta}_t - \dot{\eta}_t)^2 \, dt \right) - 3 \int_0^T \left[ \dot{\eta}_t - \dot{\eta}_t \right] \left[ \dot{\eta}_t - \dot{\eta}_t \right] \, dt
\]
\( - 6 \int_0^T \left[ \dot{\eta}_t - \dot{\eta}_t \right] \left[ \dot{\eta}_t - \dot{\eta}_t \right] \, dt \). 

Then the remaining contribution to the option price is
\[
\int_0^T Q^{(2)}(s, \kappa \xi, \xi') \, ds = \int_0^T \left[ \int_0^T \kappa(s, \dot{\eta}) \, ds \right] \left( \kappa(s, \dot{\eta}) \right)
\]
\( + \int_0^T \left[ \kappa(s, \dot{\eta}) \right] \left( \kappa(s, \dot{\eta}) \right) \, ds \),
where
\[
\dot{\omega}^2 = \frac{1}{2} (\dot{\eta}_t - \dot{\eta}_t) \int_0^T (\dot{\eta}_t - \dot{\eta}_t)^2 \, dt
\]
\( + \int_0^T \left[ \dot{\eta}_t - \dot{\eta}_t \right] \left[ \dot{\eta}_t - \dot{\eta}_t \right] \, dt \). 

Here we have used \( \int_0^T (\dot{\eta}_t - \dot{\eta}_t)^2 \, dt = 0 \) to simplify (44.8b).

B.3. Equivalent volatilities. We can now determine the implied volatility for the dynamic model by mapping the problem back to the static model of Appendix B. Recall from (B.30a), (B.30b) that the value of the option is
\[
V(t, f, s) = [f - K]^\dagger + \int_0^T \left[ \left( \int_0^T \kappa(s, \dot{\eta}) \, ds \right) \left( \kappa(s, \dot{\eta}) \right) \right] \left( \kappa(s, \dot{\eta}) \right)
\]
\( + \int_0^T \left[ \kappa(s, \dot{\eta}) \right] \left( \kappa(s, \dot{\eta}) \right) \, ds \),
where
\[
f = \int_0^T Q^{(2)}(s, \kappa \xi, \xi') \, ds + \int_0^T \left[ \int_0^T \kappa(s, \dot{\eta}) \, ds \right] \left( \kappa(s, \dot{\eta}) \right)
\]
\( + \int_0^T \left[ \int_0^T \kappa(s, \dot{\eta}) \, ds \right] \left( \kappa(s, \dot{\eta}) \right) \, ds + \cdots \), 
and where we have used \( \dot{\eta} = \dot{\eta}_0 \). We chose the “effective parameters” \( \dot{\eta} \) and \( \dot{\eta}' \) so that the integrals of \( Q^{(1)}, Q^{(2)} \) contribute nothing to \( f \). The integral of \( Q^{(3)} \) then contributed \( \frac{1}{2} b \dot{\eta} \dot{\eta}' \) \( Q^{(71)}(s, \kappa \xi, \xi') \). The option price is
\[
f = \int_0^T \left[ Q^{(1)}(s, \kappa \xi, \xi') \right] + \int_0^T \left[ \int_0^T \kappa(s, \dot{\eta}) \, ds \right] \left( \kappa(s, \dot{\eta}) \right)
\]
\( + \int_0^T \left[ \int_0^T \kappa(s, \dot{\eta}) \, ds \right] \left( \kappa(s, \dot{\eta}) \right) \, ds + \cdots \),
through \( \dot{\eta} \), where
\[\dot{\omega}_0 = \frac{1}{2} b \dot{\eta} \dot{\eta}' \] 
through \( \dot{\eta} \), we can combine \( Q^{(1)} = Q^{(2)}(s, \kappa \xi, \xi') + \int_0^T \left[ \dot{\eta} (s, \kappa \xi, \xi') \right] \left( \dot{\eta} (s, \kappa \xi, \xi') \right) \), where \( Q^{(1)} \) solves the static problem
\[
Q^{(1)} \dot{\eta}(s, \kappa \xi, \xi') = -\frac{1}{4} b \dot{\eta} \dot{\eta}' \left( \frac{1}{4} f - \frac{1}{8} \dot{f} \right)
\]
\( + \int_0^T \left[ \dot{\eta} (s, \kappa \xi, \xi') \right] \left( \dot{\eta} (s, \kappa \xi, \xi') \right) \), for \( s < \xi' \),
\[\dot{\omega}(s, \kappa \xi, \xi') = 0 \] at \( s = \xi' \),
This problem is homogeneous in the time \( s \), so its solution \( Q^{(1)} \) depends only on the time difference \( \tau = \xi' - s \). The option price is therefore
\[
V(t, f, s) = [f - K]^\dagger + \int_0^T \left( \int_0^T \kappa(s, \dot{\eta}) \, ds \right) \left( \kappa(s, \dot{\eta}) \right)
\]
\( + \int_0^T \left[ \int_0^T \kappa(s, \dot{\eta}) \, ds \right] \left( \kappa(s, \dot{\eta}) \right) \, ds \),
where \( Q^{(1)} = \delta(t - \xi') \) at \( s = \xi' \),
\[\dot{\omega} = \delta(s - \xi') \] at \( t = 0 \).
The option price defined by (B.52), (B.53a), and (B.53b) is identical to the static model’s option price defined by (A.42), (A.43a), and (A.43b), provided we make the identifications
\[
v = -\dot{\omega}, \quad \rho = \dot{\eta} \dot{\eta}' \]
\( \tau_0 = \dot{\omega}_0 - s = \dot{\omega}_0 + \frac{1}{2} b \dot{\eta} \dot{\eta}' \).
in Appendix B for the original non-dynamic SABR model, provided we make the identifications

\[ \tau_u = \tau + s^2 \int_0^\tau \left( \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial t^2} \right) dt, \]  
\[ (8.56a) \]

\[ \nu \rightarrow \tilde{\nu}, \quad v \rightarrow \hat{v}. \]  
\[ (8.56b) \]

See equations (A.42 - A.43b). Following the reasoning in the preceding Appendix now shows that the European call price is given by the formula

\[ V(t,f,K) = (f-K)K \left( \frac{f-K}{\sigma_K \sqrt{t}} \right) + \sigma_K \sqrt{t} \int_1^K \left( \frac{f-K}{\sigma_K \sqrt{t}} \right) \frac{\partial^2 C}{\partial f^2} \right) \frac{\partial^2}{\partial f^2} \right) \right), \]  
\[ (8.57) \]

with the implied normal volatility

\[ \sigma(K) = \frac{a(f-K)}{f-K} \left( \frac{\xi}{\delta t} \right). \]  
\[ (8.58a) \]

\[ 1 + \frac{2y - y_1}{24} \frac{\partial^2 C_f}{\partial t^2} + \left( \frac{\partial^2 C_f}{\partial t^2} \right) \right) \frac{\partial^2}{\partial t^2} \right) \]  
\[ (8.58b) \]

where

\[ \xi = \frac{\partial}{\partial \xi} C_f, \quad \frac{\partial}{\partial \xi} C_f = \log \left( \frac{\sqrt{1 - \frac{1}{2} \xi^2} + \xi \sqrt{1 - \frac{1}{2} \xi^2}}{\frac{1}{2} \xi^2} \right). \]  
\[ (8.58c) \]

\[ \tilde{v} = \sqrt{\frac{2}{\nu}} \frac{\partial^2 C_f}{\partial t^2} + \frac{\partial^2 C_f}{\partial t^2} \frac{\partial^2}{\partial t^2} \right) \right), \]  
\[ (8.58d) \]

Equivalently, the option prices are given by Black’s formula with the effective Black volatility of

\[ \sigma(K) = \frac{a(f-K)}{f-K} \left( \frac{\xi}{\delta t} \right). \]  
\[ (8.58a) \]

\[ 1 + \frac{2y - y_1}{24} \frac{\partial^2 C_f}{\partial t^2} + \left( \frac{\partial^2 C_f}{\partial t^2} \right) \right) \frac{\partial^2}{\partial t^2} \right) \]  
\[ (8.58c) \]

\[ \tilde{v} = \sqrt{\frac{2}{\nu}} \frac{\partial^2 C_f}{\partial t^2} + \frac{\partial^2 C_f}{\partial t^2} \frac{\partial^2}{\partial t^2} \right) \right), \]  
\[ (8.58d) \]
